Abstract

Firms in developing countries face uncertainty in whether and when workers arrive at work. Such irregularity can be costly to firms, especially when production requires coordinating labor inputs. This paper tests whether and how irregular labor supply affects firms' ability to coordinate workers and firm outcomes. I run a randomized experiment with 92 manufacturing firms in India. Firms are organized as production lines. Yet, on average, three in five workers arrive after their firm's start time. Workers in treatment firms are offered a daily incentive equivalent to 20% of earnings conditional on arriving by the start time for four weeks. Incentives increase timely arrival from 41% to 59% of worker-days, driven by workers who arrived late at baseline. Worker output increases by 24% for all treatment firm workers, including those who arrived early at baseline and did not change their arrival times in response to the incentive. These spillovers from late to early workers are concentrated in firms where late workers perform tasks upstream in the production line, suggesting irregular labor supply creates hold-ups within firms. Treatment firms produce 29% more output, receive 21% more new orders and have 40% fewer delayed orders. Findings suggest that irregular labor supply hurts firm output, but coordinating worker arrival times can be costly given workers' strong preference for flexibility.

I am extremely grateful to my advisors, Jeremy Magruder, Ted Miguel and Aprajit Mahajan for their advice and encouragement throughout this project. I would also like to thank Sydnee Caldwell, Marco Gonzalez-Navarro, Supreet Kaur, Utkarsh Kumar, Alex Mas, and participants at the Development and Labor Lunch at UC Berkeley for many helpful comments and discussions. I am extremely grateful to K. Prakash, Apoorva Limaye and Suganya Venugopal for their support and hard work on this project. I gratefully acknowledge funding from the Weiss Fund for Research in Development Economics, the International Growth Centre (IGC), Private Enterprise Development in Low Income Countries and the Structural Transformation and Economic Growth initiatives at the Center for Economic and Policy Research and the Center for Effective Global Action at UC Berkeley. IRB approval was obtained from the Committee for Protection of Human Subjects at UC Berkeley and Institute for Financial Management and Research, India. AEA Trial Registration # AEARCTR-0015588.

1 Introduction

Labor supply to firms in developing countries is highly *irregular*. Firms face high rates of absenteeism and separation, indicating irregularities along the extensive margin – workers' choice of which days to work or whether to stay in a firm (Breza and Kaur, 2025). Even when workers are present at work, their labor supply can be irregular along the intensive margin – when they arrive at work, or how many hours they choose to work on a given day. Irregular arrival times have been observed empirically across several settings but are relatively understudied in the literature.[1]

Despite the prevalence of irregular labor supply along both these margins, there is little causal evidence examining whether and how it affects firm outcomes. Irregular labor supply may have direct effects on firm output if workers who arrive late work fewer hours and produce less. These costs may be amplified when production relies on complementarities between labor inputs (Kremer, 1993). For example, in assembly lines, one worker's late arrival can hold up other workers on the line.

This paper studies how irregular labor supply affects firms' ability to effectively coordinate production, and firm outcomes. I answer this question in the context of a large garment manufacturing cluster in India comprising small-medium firms. Production is organized in batch processing lines where each worker performs a distinct operation on the garment. Operations must be done sequentially to produce a finished garment, making a worker's output dependent on both their own and their co-workers' labor supply decisions. For example, the output of workers performing downstream operations depend on those performing upstream operations, and therefore their labor supply decisions.

Workers are paid operation specific piece rates, and are neither incentivized based on the number of finished pieces, nor explicitly incentivized to arrive by their firm's start time. As a result, worker arrival times at the firm are highly dispersed, ranging from 3 hours early to 5 hours late, with a 10-90 gap of 135 minutes. In my sample, arriving after the firm's start time (henceforth referred to as "late arrivals", or "being late") is at least as common as absenteeism: workers are absent on 30% of worker-days, and late on 44% of worker-days conditional on being present. Survey responses suggest that late arrivals reflect important time-commitments outside of work (such as household and domestic care responsibilities), as opposed to behavioral reasons or tardiness. Anecdotally, workers express a strong preference

[1] For example, among casual day laborers (Cefala et al., 2024), government employees (Chaudhury et al., 2006), and factory workers in the setting of this paper.

for flexible work schedules as the main reason for late arrivals.[2]

These two features of the setting present a puzzle. Batch processing lines imply gains from coordinating worker arrival times. At baseline, 90% of owners report they would like their workers to start work at the same time. About 40% cite late arrivals among the top three challenges faced in running their business. Yet, firms do little to coordinate arrival times: 80% of owners allow workers to be more than 30 minutes late and almost none strictly enforce common start times. Owners correctly attribute this to workers' strong preference for flexibility: 52% believe that enforcing common start times would cause workers to leave the firm or refuse to work there. Taken together, these may reflect (1) an absence of gains from coordination, (2) a compensating differential for giving up flexible schedules that is too high for firms to pay, or both.

I conduct an experiment with 92 firms comprising 600 workers to test whether reducing lateness generates coordination gains within the firm, and improves firm outcomes. I incentivize workers in 46 randomly selected treatment firms to arrive by a fixed start time for a period of 4 weeks. Treatment incentives are designed as a daily bonus equivalent to 20% of workers' average daily earnings, paid conditional on arriving at the firm by the owners' work start time (hereafter, preferred start time), elicited at baseline. Workers in control firms receive unconditional transfers during the treatment incentive period, matched to a randomly chosen treatment firm each week to ensure that treatment effects are not driven by income effects on worker output.

I collect daily data on worker attendance, arrival times, task assignments and production output for 6-weeks: 2 weeks before the incentives, and the 4-week incentive period. I estimate the effect of the incentives on labor supply (timely arrival, attendance and daily work hours) and production outcomes (worker and firm output, earnings, and order-completion delays) using a difference-in-differences specification with worker and time fixed effects.

This experimental setup allows me to address both explanations of this puzzle. Comparing production outcomes between treatment and control firms directly tests for gains from timely arrival, the primary goal of this paper. In addition to this, workers' labor supply response to the incentives reveals how much they value flexible arrival times. Treatment firm workers who take up the incentive value flexibility at no more than 20% of daily earnings, while those who don't value flexibility at more than 20% of their earnings. I chose a single,

[2]This is consistent with prior work documenting that workers in developing countries have a greater demand for flexibility, given the prevalence of health shocks (Breza and Kaur, 2025), social pressure to attend cultural/family events (Goraya et al., 2025), and gender norms around domestic responsibilities (Ho et al., 2024).

large incentive amount to maximize power for the first test. The amount was decided based on pre-piloting discussions with firm owners about the minimum amount needed to shift arrival times at the firm. The incentive is therefore costly by design, and it is not intended to be a profit-maximizing contract for firms.

I find that the incentives successfully encourage workers to arrive on time in treatment firms. Timely arrival increases by 43% relative to control firms (18 percentage points). This translates to 1 additional worker out of 5 workers on average being present at the firm before the preferred start time. Further, workers change their labor supply entirely along the intensive margin by arriving earlier at the firm. There is no change in attendance rates for the average worker, and a small but imprecise increase in daily work hours that partly offsets the amount by which workers were late at baseline.[3]

To identify who responded most to treatment, I classify workers as "Early", "Late", and "Very Late" based on their average arrival times during pre-incentive weeks. The timely arrival effect is driven entirely by "Late" and "Very Late" workers, on whom the incentive was most binding: "Late" and "Very Late" workers are 54% (21 p.p) and 88% (35 p.p) more likely to arrive on time, and thus work 20 minutes and 43 minutes more per day respectively compared to the average control worker. Finally, "Early" workers do not change their labor supply in response to the incentives.

This increase in timely arrival in treatment firms results in a meaningful decline in dispersion in arrival times. Total dispersion in worker arrival times, measured as the difference in arrival times between the earliest and the last worker, decreases by 22 minutes (17% of the control mean). This is driven by the last worker arriving on average 14 minutes earlier in treatment firms, a 29% reduction relative to the control mean of 47 minutes. Incentives thus improve coordination in worker arrival times by shifting the arrival time distribution to the left.

As a result, weekly output per worker in treatment firms increases by 0.26 standard deviations, a 24% increase relative to the control mean (equivalent to 930 additional pieces per week).[4] Weekly worker earnings increase by 9%, though the estimate is imprecise. The increase in output per worker partly reflects an increase in per-hour productivity: the effect on output survives even after scaling by weekly hours worked, but is smaller.

Crucially, the incentives generated positive spillovers among workers in treatment firms.

[3]Workers in treatment firms work on average 17 minutes longer per day than control firm workers, a 5% increase relative to the control mean. The average worker arrives 8 minutes late during pre-incentive weeks.

[4]Worker output sums the number of pieces stitched across all operations in a week, and is standardized to pre-incentive, product-level means.

The increase in worker output is realized by all workers, including both "Early" workers who did not respond to incentives, and those who arrived late at baseline and responded most to the incentives. Gains in worker earnings and output per hour follow a similar pattern of spillovers from "Late" to "Early" workers.

These spillovers reflect gains from improved coordination along the production line. I use characteristics of firms' production process to identify firms where lateness is more likely to create hold-ups on other workers, hereafter, "Bottleneck" firms. I classify firms as Bottleneck firms if any worker who performs upstream tasks in the production line at baseline is a "Late" worker. If there are gains from coordination, I expect to see output gains among "Early" workers to be driven by Bottleneck firms. In remaining firms where lateness does not create hold-ups on other workers (hereafter, "Non-Bottleneck" firms), there should be no spillovers to "Early" workers.

Consistent with the prediction above, I find that the effect on weekly output for the average worker is larger in Bottleneck firms (0.36 SD) than in Non-Bottleneck firms (0.12 SD, not statistically significant). More importantly, *which* workers experience this gain differs across the two samples. I find that spillovers from "Late" to "Early" workers only exist in Bottleneck firms: both "Early" and "Late" workers experience a 0.39 SD and 0.34 SD increase in weekly output respectively. These effects are not statistically distinguishable from each other. Adding further support for the coordination channel, I find that in Non-Bottleneck firms, gains in worker output are concentrated only among "Late" workers, with no increase in output for "Early" workers. Gains in earnings and output per hour are also more pronounced in Bottleneck firms, consistent with improved coordination along the production line. Bottleneck and Non-Bottleneck status are not randomly assigned, and the two sub-samples differ on some baseline characteristics. However, these results are robust to controlling for baseline differences, and to alternate definitions of hold-ups within the firm.

These gains in worker output translate almost one-to-one to gains in total firm output.[5] I find a 0.30 standard deviation increase in weekly firm output: a 29% increase relative to the control mean (equivalent to $\approx$ 700 pieces). Similar to worker-level outcomes, gains in total firm output are larger in Bottleneck firms, suggesting that the firm also stands to gain from improving coordination in worker arrival times.

Treatment facilitates timely completion of orders. Specifically, treatment reduces the probability of completing an order after the owner's planned delivery date by 10 percentage

[5]Total firm output is measured as the total number of finished pieces produced by all workers in the firm, and standardized to pre-incentive, product-level means.

points, a 40% reduction relative to the control mean. Timely completion of orders is crucial in this setting because most firms rely on repeat relationships with their clients to procure new orders. Consistent with this, I find evidence that treatment firms receive more new orders: the quantity of new orders received during the incentive weeks increases by 0.27 SD, a 21% increase relative to control firms ($\approx$ 880 pieces).

Finally, I find that weekly firm revenues increase by INR 3,257 (8% relative to the control mean), while total labor costs, *excluding* the incentive paid to treatment workers, increase by INR 1,640 (9% relative to the control mean). Weekly firm profits, excluding incentive payments made to workers, increased by $\approx$ INR 1,600 (8% of the control mean), suggesting irregular labor supply may reduce firm profits, although the effect is noisy. However, paying a 20% bonus as incentives for timely arrival outweighs revenue gains, resulting in a negative effect on profits of $\approx$ INR 981. This suggests that the 20% incentives I offered in the experiment are too costly for firms to adopt. Moreover, despite high incentives, 25% of workers in treatment firms chose to continue arriving late. This is consistent with workers placing a high value on flexible arrival times, but does not rule out other contract designs or incentive amounts that might be profitable for firms.

Firm owners recognize this trade-off: treatment firm owners agreed that incentives were valuable, yet their average stated willingness to pay for similar incentives was less than a third of the incentives I offered. In a longer-term follow-up survey, there was no take-up of any kind of financial incentives among treatment firms, beyond verbal encouragement. This is consistent with high cost of incentives. However, enforcing common arrival times without any incentives is also difficult: firms compete in an active labor market where most workers value flexible work schedules, and nearly all firms offer such flexibility. This makes it difficult for a single firm to deviate without facing difficulties in hiring or retaining experienced tailors.

Overall, the findings suggest that returns to coordination within the firm are large and economically meaningful. However, workers have a strong need for flexible work schedules, and report that this arises from the poor quality of public infrastructure and missing markets for childcare. Thus, firm-level incentives alone may not be a sustainable solution.

Related Literature and Contributions: This paper is most directly related to the literature on barriers to firm growth in developing countries. I extend the literature examining the association between irregular labor supply on firm outcomes (Krishnaswamy, 2019; Goraya et al., 2025) in two key ways. First, I provide causal evidence that firms benefit from timely worker arrival through coordination gains along the production line using high frequency data on worker labor supply and task assignments within the firm. This extends the

finding from previous work that adverse effects of worker absenteeism are stronger in firms and industries with larger co-worker complementarities. A small set of studies have examined the effect of attendance incentives among government workers in developing countries (Banerjee et al., 2008; Duflo et al., 2012; Dhaliwal and Hanna, 2017). While these studies used time-stamped monitoring to verify worker attendance, their focus was exclusively on attendance and not timely arrival. To the best of my knowledge, this is the first paper to experimentally test the effects of timely arrival on firm outcomes in the private sector.

A large body of work documents search and hiring frictions in low-income countries (De Mel et al., 2019; Hardy and McCasland, 2023; Bassi and Nansamba, 2022; Caria and Falco, 2024; Carranza et al., 2020). I add to this work by documenting that even conditional on forming matches, firms face barriers to coordinating workers. To the extent that coordination becomes costlier with scale (Lucas, 1978), this can have important implications for firms' ability to scale their workforce.

I also contribute to the growing literature on the internal organization of small, informal firms in developing countries, building on recent work such as Bassi et al. (2022, 2023). In particular, Bassi et al. (2023) find limited labor specialization in multi-worker Ugandan manufacturing firms. Instead, these firms are organized as a collection of self-employed individuals, and are unable to realize gains from team production. By contrast, I study a setting with labor specialization along a sequential production line and provide evidence for coordination gains within firms using novel data on the internal organization of production.

Finally, this paper speaks to work on the provision of flexible work arrangements by firms and labor supply preferences (Mas and Pallais, 2020). Workers' demand for flexibility has been documented across several different contexts (Mas and Pallais, 2017; Ho et al., 2024; Baysan et al., 2024; Wiswall and Zafar, 2018). I add to this work by showing that while workers prefer flexible work arrangements, their own labor supply decisions create externalities on their co-workers. This is consistent with the idea that despite fixed-schedules being a dis-amenity for workers individually, there are potential gains to themselves *and* the firm.

Structure of the Paper. The remainder of the paper is organized as follows: section 2 describes the study context and data, section 3 outlines a framework for how lateness may affect firm production, section 4 describes the experimental design and implementation, and section 5 lays out the empirical strategy. section 6 presents the main results and section 7 concludes.

2 Setting, Data and Descriptive Evidence

This section describes the setting of the paper, data collected as part of the experiment and descriptive evidence on the organization of production.

2.1 Organization of Production in Tiruppur

The setting of my study is Tiruppur, a major garment manufacturing hub in the southern state of Tamil Nadu, India. Production in Tiruppur is highly decentralized and carried out by sub-contracted units (called job-work units) specializing in distinct stages of the supply chain, such as knitting, dyeing, cutting, stitching, and packing. This paper focuses on job-work units that specialize in stitching, the most labor-intensive stage of production. Firms receive cut pieces of fabric from a client/buyer (hereafter referred to as an order), and are responsible for stitching pieces into the finished garment and delivering the order back to their client. Firms specialize in broad product categories such as t-shirts, bottomwear, innerwear, or kids wear, and are paid piece-rates per unit of finished garment.

Production is organized in batch processing lines, where each worker performs a distinct operation on the garment in batches of 80-100 pieces before passing the batch to the next worker. Operations (hereafter, tasks) need to be performed sequentially in order to produce a finished piece of garment. The main production workers in these firms, and the focus of the study, are tailors, who perform designated tasks along the production line. Figure 1 depicts a stylized production line for a firm producing t-shirts. In this example, the firm receives cut pieces of fabric which are processed in 4 steps (tasks). One tailor first attaches the shoulders, passing on a batch to a second tailor who stitches the sleeves, followed by a third tailor who attaches the collar, and finally the fourth tailor who sews the bottom hem.

Tailors are paid piece rates for each individual task they perform (for example, attaching shoulders), and not the number of finished pieces of the garment. Although firms have set operating hours in the status quo, tailors are not explicitly incentivized to arrive at a common start time. As a result, despite the sequential nature of production, the pay contract does not give tailors any private incentive to coordinate their arrival times.

Firms also hire non-production workers called "helpers". Helpers are unskilled workers whose primary role is to support the production line by preparing the fabric and moving work-in-progress inventory to the next worker. While helpers are not the focus of the study, I utilize the presence of production and non-production tasks in the production process to measure tailor's time-utilization within the work day. Specifically, tailors occasionally

perform non-production tasks at the firm if their batch is not ready.

The study takes place in 4 urban and peri-urban neighborhoods in Tiruppur which were identified as dense clusters of small-medium stitching firms during prior area mapping exercises. I target firms employing between 5-20 workers, with at least 2 tailors who are not related to the firm owner. All firms that satisfy these criteria were eligible for the experiment. While these firms are larger than modal small developing country firm, they employ $\approx$ 30% of the workforce within the garment industry in Tiruppur (Economic Census, 2013-14). Such organization structures are common in many industrial clusters around the world, for example Nadvi and Schmitz (1994); Banerjee and Munshi (2004); Chaudhry and Woodruff (2013); Atkin et al. (2017).

2.2 Data and Definitions

To document day-to-day irregularities in labor supply and how it affects the internal functioning of firms, I implement a 6-week experiment with 92 firms and track labor supply and production outcomes throughout this period. I conduct a baseline survey before the 6-week period. The first 2 weeks are pre-incentive weeks (also referred to as baseline), and workers are paid incentives during the last 4 weeks based on their firms' treatment assignment. Since firms do not typically maintain any internal attendance, arrival time or production records, I designed and implemented an extensive data collection exercise spanning these 6-weeks. This section outlines the data collected from firms and workers and defines key variables used in the paper.

Baseline Survey: I conduct a baseline survey with firm owners to capture owner and firm characteristics and collect a roster of all production workers (tailors). The worker roster is updated throughout the 6-week period to track workers joining and leaving the firm. The survey asks all firm owners to report when they would like all their workers to arrive at the firm, hereafter referred to as the firm's start time. This time was announced to all workers during worker baseline surveys, which were conducted shortly after the owner baseline survey. I measure lateness relative to this time: a worker is late (on-time) on a given day if they arrive after (before) their firm's start time. Arrival time deviation measures the difference in minutes between worker arrival times and the start time.

Order, Task and Piece-Rates Data: During the baseline survey, I record a roster of all distinct styles that the firm is currently producing. For each style, I record the piece rate that the owner receives for a finished stitched piece and its task sequence – a list of

tasks that need to be performed to produce the finished product, the order in which they are performed, and task specific piece rates paid to workers. I combine information on piece rates with production data to construct worker earnings, firm revenues and total labor costs (see below). I use information on the sequence of tasks to identify tasks that are upstream (downstream) in the production line.

Daily Attendance and Production Data: During the 6-week period, enumerators visit firms three times a day to workers' attendance, arrival time, break times during the day, and daily output (by product-task). Arrival times and attendance are recorded by enumerator observation; remaining data is self-reported by workers.

Daily output from stitching tasks is recorded for all production workers, including firm owner and helpers where applicable. In addition to production output, I also record whether the worker did any other non-production tasks at the firm, such as helper work, receiving or delivering raw material/finished pieces, machine repair, purchasing inputs, etc. I use these data to construct my main labor supply and production outcomes, which I describe below:

a) Labor Supply Outcomes: The three primary labor supply outcomes are timely arrival, work hours and attendance, and are measured daily. Timely arrival is an indicator for being present at the firm, *and* arriving before the start time. Attendance is an indicator for whether the worker was present at the firm that day. Daily work hours are defined as the total work duration net of the total duration of breaks taken during the day, and coded 0 when workers are absent.[6]

b) Production Outcomes: The three primary production outcomes, worker output, output per hour and earnings are aggregated to the weekly frequency. Worker output (SD) is measured as the total quantity of pieces stitched by the worker in a week, across all tasks (and products), and normalized to pre-incentive product level means.[7] Output per hour is worker output in standard deviation units, scaled by total weekly hours worked. Worker earnings are constructed by adding the product of task-specific output and piece rates over the week.

c) Total Firm Output (SD): I construct total firm output by aggregating total quantity produced in two ways: (1) across *all* tasks, and (2) for the last task in the production

[6]Breaks include any time taken for lunch, tea, or other reasons for which the worker left the firm. Workers rarely do other non-tailoring tasks for the firm during breaks (5% of worker-days).

[7]Since firms produce different types of products, I normalize weekly worker output to pre-incentive, product-level means and standard deviations to account for any level differences in task speed and production quantity across product types.

line. These measures correspond to total units stitched in the firm, and total units of the finished garment respectively. Firm revenues and total labor costs are computed as the product of piece rates earned by owners and workers, and the total quantity of the last task in the production line. Both measures aggregate output across all production workers (i.e., including production by tailors, firm owners and helpers, as applicable), and are normalized to pre-incentive product level means.[8]

Orders Data: At the end of each week, I ask firm owners to report all orders received and delivered by the firm in that week. This allows me to track new orders received by firms, measured as new batches of cut-material received. For each order, firm owners report their planned and actual delivery dates. This allows me to construct a measure of delays in order delivery. I use these data to construct the following outcomes:

d) New Orders Procured (SD): Similar to production output, I aggregate the total quantity of new orders received in a week (normalized to pre-incentive product level means).

e) Delay: Delay is an indicator for whether the actual delivery date was after the planned delivery date.

Endline Survey: I conduct endline surveys with owners and workers during the last week of the study to capture their perceptions about the incentives, preferences for work schedules, changes in firm operations during the study, and changes in workers' time-use during and before the work day.[9]

Follow-up Survey: Finally, I conduct a follow-up survey where I ask firms (retrospectively) about measures they adopted to encourage timely arrival, and long-term firm outcomes such as business finances, survival, temporary closures, and worker turnover.

2.3 Descriptive Evidence on Worker Arrival Times

In this section, I document stylized facts about late arrivals and the reasons that contribute to lateness.

[8] Weekly firm revenue is the product of total firm output and the total piece rate that owners earn, and weekly labor cost is the product of total firm output and the total piece rate that workers earn (across the product's constituent tasks) in each week.

[9] For a subset of firms, endline surveys also included questions asking firm owners to predict which workers will be present and arrive on time the next day, and asking workers why they arrived late during the past week.

Fact 1: There is substantial lateness and dispersion in tailor arrival times at work. Given that workers' piece-rate compensation structure does not explicitly incentivize common arrival times, late arrivals are common. Workers are late on 59% of worker-days during these pre-incentive weeks. Conditional on being present, workers are late on 44% of worker-days. I also observe substantial dispersion in worker arrival times around the start time. Figure 3 plots the distribution of worker arrival times deviated from the firm's start time, conditional on being present: the 10-90 gap of this distribution is 135 minutes.

Late arrivals reflect workers exercising flexibility in arrival times. The need for flexibility arises from important time commitments outside work. Figure A1a shows that the most common reasons for arriving late on any given day are household responsibilities and sickness in the household, followed by disruptions in transportation arrangements. Given gendered norms around domestic and caregiving work, these burdens fall disproportionately on women. Reasons related to tardiness, such as waking up late or losing track of time are rarely reported.

Firm owners prefer that workers arrive at the same time, but are unable to enforce this in the status quo. Flexible work schedules are the norm in this local labor market: 85% of owners report being flexible with work timings in the baseline survey. However, firms allow lateness because of labor market competition from other firms: owners are concerned that enforcing common arrival times without pay would result in workers leaving the firm, possibly harming their reputation in the market and making future hiring difficult (Table A1). 55% of workers in my sample have previously worked in large, export factories that enforce strict work schedules, and reported leaving those jobs because they prefer flexible schedules (Figure 4).

Fact 2: Firm owners know who tends to be late, but exact arrival times are unpredictable. In the worker-day panel, the correlation between timely-arrival across two consecutive workdays is 0.53 (SE = 0.04, p-value < 0.001). This correlation shrinks to 0.04 (SE = 0.041, p-value = 0.175) after accounting for worker fixed effects. This suggests that lateness is a characteristic of workers that can be learned by owners. In surveys, firm owners can identify which workers are typically late.

Motivated by this, I use average pre-incentive arrival times to classify workers into three types: "Early", "Late", and "Very Late" workers. "Late" and "Very Late" are indicators for workers whose average pre-incentive arrival times were between 0 and 30 minutes, and above 30 minutes after the start time, respectively. Consistent with Fact 1, Late and very late workers are significantly more likely to be female and married than early workers (Table A5).[10]

[10]There are no differences in commute times by gender or arrival time group, suggesting that arrival times

I use these classifications later for heterogeneity in treatment effects.

While owners can identify "Early", "Late" and "Very Late" workers, they cannot accurately predict actual arrival times on any given day. For example, owners could correctly predict which workers will arrive on time the next day 63% of the time, and which workers will arrive on time for the entire week only 23% of the time. Owners are also over-optimistic about timely arrival, and more so for "Late" workers: owners reported 52% of their workers will be on time for the entire week, compared to actual on-time rate of 41%. This gap is larger among workers who are late on average: 43% predicted versus 23% actually on time. On the other hand, owners are better at predicting worker attendance: they correctly predict who will be present the next day 87% of the time, and for the entire week 57% of the time.

3 A Framework on How Lateness Affects Production

Lateness can affect production both directly and indirectly. Pre-incentive data on daily work hours and output suggests that "Late" and "Very Late" workers work fewer hours, but don't produce more pieces per hour relative to "Early" workers (Table A5). Thus, regardless of other workers' arrival times, "Late" and "Very Late" workers may result in lower firm output.

However, given the sequential nature of production, late arrivals may also have indirect effects on other workers in the firm. Lateness on upstream tasks in the production line can hold-up workers on downstream tasks. This may increase idle time if "Early" workers wait for the "Late" worker to complete upstream tasks. Further, it may limit downstream workers' ability to specialize in their main task (defined as the modal task they worked on during pre-incentive weeks) if "Early" workers need to fill in for the late upstream task worker. On the other hand, lateness on downstream task stations doesn't hold up other workers on the production line, but may hold-up the delivery of finished garments, and thus create delays in order completion.

This is consistent with owners' beliefs about how lateness affects production at their firm. When asked why coordinated timings would help increase production, 66% of owners suggest a reduction in idle time, and 51% suggest increased task specialization as possible mechanisms (Figure 5b). Additionally, 40% owners also allude to uncertainty about whether and when workers will arrive at the firm as another mechanism. Coordinated timings can help owners plan and deliver orders on time, which helps them receive more orders in the

observed in status quo are not driven by commuting frictions, but are likely driven by time commitments in the household before the start of the work day.

future.

3.1 Challenges in Adapting to Lateness

One obvious response to lateness might be to enforce common arrival times, either by penalizing, or firing workers who arrive late. However, as discussed in section 2.3, this is not possible given the current market equilibrium firms operate in. Instead, firms can re-organize production to adapt to lateness, but their ability to do so may be limited.

First, firms can change the sequence in which tasks need to be performed, so that tasks performed by "Late"/"Very Late" workers can be done towards the end of the production process. However, firms cannot change the sequence in which tasks need to be performed, as the sequence depends on how fabric is cut, a decision made by their clients.

Second, firms can instead re-assign workers to tasks such that workers who arrive early are assigned to upstream tasks, and those who arrive late are assigned to downstream tasks. However, worker-tasks assignments are largely fixed, in that workers specialize in their main task. Figure A2 shows that 77% of workers have one main task at the firm, defined as the modal task they worked on during pre-incentive weeks. There is some task-sharing observed at baseline: Figure A3 shows that on average, workers produce 71% of the day's output from their main task, and the remaining on other tasks. This form of adaptation is necessary for firms to operate given day-to-day fluctuations in absenteeism and lateness. Conversations with workers suggest that task-sharing is not preferred for two reasons. First, workers recognize there are gains from specializing in a single task relative to performing multiple tasks. Second, there are informal norms against task sharing, particularly when tasks differ in piece-rates: a worker who typically performs a high piece-rate task might dislike her work being covered by a co-worker when she is late. Figure A4 also suggests there is no correlation between whether a person is late and the sequence of the task they perform at the firm, consistent with task-assignments not changing in response to daily fluctuations in arrival times. Finally, task-sharing might not always be possible in practice if skills are not transferrable across tasks.

The main way in which firms do adapt to lateness is by maintaining work-in-progress inventory between work-stations. This is a crucial feature of batch processing lines that allows firms to adapt to both worker absenteeism and lateness more flexibly compared to assembly lines (as discussed in Chaudhry and Woodruff (2013)). Maintaining a sufficient pile of material for workers who arrive early may mitigate indirect effects of lateness. While I do not have a direct measure of inventory levels within the day, data on weekly orders allows

me to identify the number of distinct orders that are in production each day, an alternate measure of inventory. I observe firms having single orders in production on about half of firm-days, allowing me to assess the extent to which firms successfully adapt to lateness. Pooling all days from pre-incentive weeks and control firms, I find that output and earnings for workers on downstream tasks is lower on days when the upstream task worker is late, and the correlation is much more pronounced on days when the firm has only one active order in production (Table A6).

This suggests that firms may only be able to partly mitigate indirect effects from lateness.

3.2 Two Definitions of Hold-Ups Created by Late Arrivals

To test for the presence of indirect effects of lateness, I leverage the sequential nature of production, and limited skill transferability across tasks to identify firms where lateness is more likely to create hold-ups for other workers. I define hold-ups created by lateness in two ways:

1. Bottlenecks created by lateness on upstream tasks

The first definition is based on where lateness occurs on the production line. I define a "Bottleneck" firm as a firm with at least 1 upstream task worker who is also "Late" or "Very Late" at baseline. An upstream task worker is a worker whose main task (as defined at baseline) is an early sequence task in the production line. The complement to this is a "Non-Bottleneck" firm, where no upstream task worker is late. Since firms produce different products, and task sequences may vary across firms, I identify upstream (downstream) tasks as all tasks that appear before (after) a "cut-off" task. Upstream task cut-offs are defined based on tasks that must be done to proceed with remaining tasks (e.g., the task 'attaching shoulders' must be done before all other tasks to make a t-shirt). Likewise, downstream task cut-offs are defined based on tasks that must be done in order for a garment to be considered finished (e.g., bottom hems on a t-shirt, or elastic bands on pants).[11]

This definition yields two predictions:

1. If lateness creates negative spillovers along the production line, reducing lateness would have both direct and indirect effects on worker output. Spillovers should only be present in Bottleneck firms, and not in Non-Bottleneck firms.

[11] Figure A5 shows that my classification of upstream and downstream tasks maps well to relative task orders in the production line.

2. If lateness does not create negative spillovers along the production line, reducing lateness would only have direct effects on worker output. However, reducing lateness may help reduce order-completion delays.

2. Spillovers are more likely when tasks sharing is limited

The second definition leverages limited substitutability of worker skills across tasks in the production line. I classify tasks within a firm into two types: Simple and Complex tasks. Complex tasks are tasks performed on a singer machine (as opposed to Overlock or Flatlock machines for Simple tasks). Completing a complex task for one piece of the garment involves more precision and time (Table A7). As a result, complex tasks are paid a higher piece rates and are only performed by experienced tailors skilled at using the singer machine. Simple tasks can be performed by all tailors, however, Complex task tailors dislike performing lower piece-rate tasks. As a result, there is little crossover between both types of tasks. Further, Complex tasks tailors are significantly more likely to arrive early at the firm than Simple task tailors (Table A7), possibly because higher piece-rates incentivize them to work longer hours.

I classify firms as "Complex Task" firms if at least one product they produce at baseline has a complex task, and "No Complex Task" firms otherwise (44 and 47 firms respectively)[12]. Among Complex Task firms, I further distinguish firms where the complex task follows a simpler task in the production line ("Complex Downstream", 27 firms) from the remaining firms ("Complex Upstream", 17 firms). An advantage of this definition is that unlike the Bottleneck classification, it is not mechanically related to the extent of lateness within the firm at baseline.

This definition yields one prediction: No Complex Task firms are better able to adapt to lateness, since workers can be easily re-assigned to other Simple tasks. On the other hand, lateness may create negative spillovers in Complex Task firms since workers cannot easily be re-assigned across Simple/Complex tasks. Further, since lateness is more likely to occur on Simple task stations, negative spillovers should be more likely to occur in Complex Downstream firms. Spillovers should only be present in Complex Task and Complex Downstream firms, and not in No Complex Task firms.

Finally, the two definitions are not strongly or significantly correlated with each other (correlation = 0.04; Table A8), and serve as robustness checks for each other. Treatment

[12]I am unable to distinguish between simple and complex tasks for 1 firm in the sample, and drop that firm from this analysis.

status does not predict either classification (Table A8), and treatment and control firms are largely balanced on baseline characteristics within each subsample (Table A9 and Figure A6).

4 Experiment Design and Sample Characteristics

Given a context where workers express strong preferences for flexibility, I design an experiment with high-powered incentives to test for the effect of late arrivals on firm outcomes. Changing firms' status quo compensation structure is difficult to implement, and such changes may require other organizational changes in the firm (e.g., increasing base pay, or hourly monitoring). Thus, I chose to implement a simple, daily bonus to incentivize timely arrival. Scoping and pre-piloting work with firm owners suggested a daily bonus worth INR 100 as the minimum amount needed to incentivize workers to arrive on time.

Experimental Design and Implementation. Firms are randomly assigned to one of two treatment groups - (T) Treatment (n = 46), and (C) Control (n = 46). All workers in treatment firms were eligible to receive a daily bonus of INR 100-150 (equivalent to 20% of their *average* daily earnings) if they arrived at the firm and started work by the company's preferred start time. Thus, the incentive encourages both on-time arrival and attendance. The total incentive amount was paid to workers as part of their weekly earnings.[13] The unconditional incentive amount for control group firms was matched to the total realized payment made to a randomly selected treatment firm, capped at INR. 300-450 per week (half of the maximum incentive amount in treatment firms). These treatment-control firm (randomized) pairings were created separately each week. Figure 6 shows the experiment design and timeline.

The experiment was implemented in three rounds, covering 6-week periods over the course of a full year. This ensures that my results are not affected by a specific peak or lean production season. Figure 6 shows the study timeline: round 1 was implemented with 17 firms (9 treatment, 8 control) from November 2024 to January 2025, round 2 was implemented with 40 firms (19 treatment, 20 control) from March 2025 to May 2025, and round 3 was implemented with 35 firms (18 treatment, 18 control) from August 2025 to October 2025. The daily treatment incentive amount in Round 1 and Round 2 was set to INR 100, and was increased to INR 150 in Round 3.[14]

[13] All workers who were working full-time at the firm at any point during the study were eligible to receive incentives. Workers' full-time status was determined by the owner and verified by the research team using daily attendance data.

[14] Follow-up surveys were conducted between November 2025 and January 2026, and were conducted in the order that firms were recruited. Thus, the follow-up timeline ranges from 3 months for Round 3 firms,

Randomization and treatment announcement was done after owner and worker baseline surveys. Randomization for Round 1 was conducted by generating a random order of treatment/control assignments, which firms were matched to in the order in which their baseline survey was completed. Randomization for Rounds 2 and 3 was stratified on the degree of dispersion in worker arrival times around the owner's preferred work start time, using worker's usual arrival times as reported by the owner in the baseline survey. All specifications reported in the paper control for round by strata fixed effects to account for the method of randomization in each round (Bruhn and McKenzie, 2009).

Balance and Sample Characteristics. Baseline firm and worker characteristics, and balance by treatment arms are reported in Table A3 and Table A4 respectively. On average, firms hire 6 tailors, excluding owners and family members who also do stitching work at the firm. Firms have been in operation for 6-7 years and earn INR 30,000 (USD 340) in monthly profits on average. Owners directly supervise workers (that is, without a manager/contractor) in almost all firms. About 85% owners are male, 57% have completed secondary school and have 19 years of experience in the garment industry.

44% of workers in my sample are male, unlike other garment manufacturing contexts studied in the literature where the workforce is predominantly female. Workers are on average 37 years old, 94% are married, and 84% have at least one child younger than 14 years of age. Thus most workers in my sample are at a life stage with substantial care responsibilities at home. Both firm and worker characteristics are balanced across treatment and control firms.

5 Empirical Strategy

I utilize the panel structure of my data and use a difference-in-differences with worker and week fixed effects to estimate the effect of incentives on worker level outcomes.[15] I estimate the following specification:

$$Y_{i(f),t} = \alpha + \boldsymbol{\beta}\text{Treatment}_{i(f)} \times \mathbb{I}\{\text{During}\}_t + \lambda_{i(f)} + \mu_w + \mu_{dow} + \varepsilon_{i(f),t} \tag{1}$$

where $Y_{i(f),t}$ is the outcome of interest for worker i in firm f at time t, and time is either

to 12 and 9 months for Round 1 and 2 firms respectively.

[15] I also prespecified an ANCOVA specification, and that I will report the specification that yields the highest statistical power.

day or week, depending on the outcome variable. $\text{Treatment}_{i(f)}$ is an indicator that equals 1 if a firm f is assigned to treatment (fixed over time), $\mathbb{I}\{\text{During}\}_t$ is an indicator variable that takes the value 1 if the study week is an incentive week, and $\lambda_{i,f}$ denotes worker fixed effects. μ_w are study round by week fixed effects, [16] and μ_{dow} are day-of-week fixed effects (dropped from worker-week level specifications). $\boldsymbol{\beta}$ is the coefficient of interest, and standard errors $\varepsilon_{i(f),t}$ are clustered at the firm level. Worker fixed effects absorb round by strata fixed effects.

I use a similar specification for firm-level outcomes:

$$Y_{f,t} = \alpha + \boldsymbol{\beta}\text{Treatment}_f \times \mathbb{I}\{\text{During}\}_t + \lambda_f + \mu_w + \varepsilon_{f,t} \tag{2}$$

where indices and variables are defined as above, λ_f denotes firm fixed effects, and standard errors $\varepsilon_{f,t}$ are clustered at the firm level. Firm fixed effects absorb round by strata fixed effects.

6 Results

This section presents results from the experiment. I first show how workers responded to the incentives. I then report effects on production outcomes, and test whether these effects reflect fewer hold-ups along the production line. Next, I report the effects on firm output and profits. Finally, I bring these results together to explain why firms tolerate lateness.

6.1 Incentives Increase Timely Arrival but not Attendance

Table 1 presents the effect of the incentives on timely arrival, daily work hours and attendance. Timely arrival in treatment firms increases by 18 percentage points (column 1), a 43% increase in timely arrival relative to the pre-incentive control mean (41 percentage points). Column (3) reports the treatment effect on daily work hours. Workers in treatment firms worked an additional 0.28 hours (17 minutes) relative to workers in control firms, but this effect is not statistically significant. Finally, I find no effect on attendance (column 5).

Figure 7b plots the distribution of worker arrival times (conditional on being present) in 15-minute intervals around the preferred start time for treatment (solid lines) and control (dashed lines) firms. This provides a visual representation of the treatment effect on timely

[16] Study weeks take the value 1 to 4 for the 4 incentive weeks, 0 and -1 for weeks prior to incentives.

arrival. The distribution of worker arrival times shifts to the left. Given the average size of 6 tailors per firm and 71% attendance rate (4 out of 6 workers present on average), this means that 1 additional worker arrives within 15 minutes of the start time in treatment firms.

Next, I examine whether these effects vary by baseline lateness. Columns 2, 4, 6 in Table 1 report heterogeneity in labor supply response for "Early", "Late" and "Very Late" workers. The effect of timely arrival is driven entirely by workers who were consistently late at baseline (column 2). "Late" and "Very Late" workers are differentially 21 and 35 percentage points respectively more likely than "Early" workers to arrive on time. This is expected since the incentives were more binding on workers who consistently arrived after the preferred start-time. The increase in work hours (reported in column 4) is larger among "Late" workers (0.37 hours/22 minutes) and "Very Late" (0.73 hours/44 minutes) workers, but not statistically significant at conventional levels.

The slight increase in work hours is driven by these subgroups of workers arriving earlier, as opposed to taking longer breaks during the workday or leaving the firm earlier. Table A10 reports the treatment effect on deviation from the preferred start time. On average, workers in treatment firms arrived 11 minutes earlier relative to control workers. This effect is driven by "Late" and "Very Late" workers (column 4) arriving 13 minutes and 28 minutes earlier relative to control workers.[17]

There are no effects on attendance for "Early", "Late" and "Very Late" workers (column 6). Notably, attendance among "Early" workers does not improve despite the fact that these workers were effectively only incentivized to be present at the firm without changing their arrival time.[18]

These results suggest that workers' labor supply response to incentives operates entirely along the intensive margin of choosing when to arrive at work and not through attendance. There is a small change in work hours that approximately offsets the amount by which

[17]There is evidence that "Very Late" workers compensate for arriving earlier by taking one additional break during the day, resulting in an 8 minute increase in the total duration of breaks taken during the day (pval = 0.10), as reported in columns (2) and (4) of Table A11. Finally, Table A12 suggests there is no evidence that workers leave the firm before 6.30 (the modal evening tea break time after which workers may leave work early) (columns 1-2), before the firm's usual closing time (columns 3-4), or before their own usual exit time (columns 5-6).

[18]37% of worker absences are because of social functions, followed by 19% because there was no work at the firm, 18% because either the worker or a family member was sick, and 10% because of local temple/religious festivals. A majority of these reasons relate to importance of social/kinship relations, as emphasized in Breza and Kaur (2025), but it is worth noting a large fraction of absenteeism attributable to low labor demand. This matches the rate of all-day firm closures recorded in the data - 10% of firms were closed for the entire day. 40% of closures were because the firm did not have work, followed by 36% because of local temple festivals or the firm owner's personal commitments, and 10% because of power cuts.

workers were late at baseline.

A key feature of the labor supply response is that despite a bonus equal to 20% of daily earnings, a substantial share of workers did not change their arrival times, suggesting high value for flexible work schedules. Figure 8 shows that 25% of workers can be characterized as never-takers: treatment firm workers who do not arrive on time on at least 80% of the days even when offered large incentives.

6.2 Production Outcomes Improve for All Workers

Incentives raise weekly worker output for all workers in treatment firms, not only the "Late" workers who changed their arrival times in response to the incentives.[19]

Columns (1)-(2) of Table 2 report results for weekly worker output. The average treatment effect on weekly worker output is 0.26 standard deviations (statistically significant at the 5% level). In levels, this amounts to 930 additional pieces per week in treatment firms over an average of 3,874 pieces per week in control firms. This represents a 24% increase in weekly output relative to the control group mean (column 1 of Table 2).

The effect on worker output is driven equally by "Early" and "Late" workers, even though only "Late" workers responded to the incentives. "Early" workers gain 0.22 SD and "Late" workers 0.28 SD (column 2). These magnitudes are statistically indistinguishable.

These increases in worker output hold even after scaling for hours worked, but are smaller in magnitude. Columns 5-6 of Table 2 report effects on normalized weekly output scaled by weekly hours worked: output per hour rises by 0.007 SD for the average treatment firm worker and is significant at the 10% level (column 5). This effect is similar for "Early" and "Late" workers (column 6). This suggests a small improvement in per-hour productivity for all workers.

Earnings follow the same pattern, but are smaller in magnitude and less precisely estimated. Columns 3-4 of Table 2 report results for weekly worker earnings *excluding* incentive payments. Weekly earnings increase by INR 310 (9% of the control mean) for the average worker. The effects are similar across "Early" and "Late" workers.[20] Despite not being

[19] I pool "Late" and "Very Late" workers.

[20] *Including* the treatment incentive payments, all workers in treatment firms earn INR 817 per week (see Table A15), and this effect is not statistically different for "Late" workers. These results suggest that if workers were to, hypothetically, arrive on time *without* any monetary incentives, they could have earned on average INR 310 more per week than their status quo arrival times. Depending on whether workers internalize indirect effects of timely arrival along the production line, the implied willingness to pay ranges between INR 310 to INR 817 in weekly earnings.

statistically significant, a 9% increase in earnings is an economically meaningful magnitude. Reassuringly, there is a clear rightward shift in the distribution of change in earnings for workers in treatment firms, as shown in Figure 9.

Overall, while only "Late" and "Very Late" workers changed their labor supply in response to the incentives, gains in production outcomes were experienced by all workers in the firm, including "Early" workers. This indicates the presence of positive spillovers within the firm as a result of treatment.

6.3 Spillovers reflect gains along the production line

Next, I test whether these spillovers arise from better coordination along the production line. If these spillovers reflect gains from better coordination along the production line, we should only expect to see spillover effects in Bottleneck firms. Recall, these were firms where "Late" workers performed upstream tasks at baseline.Table 3 replicates results on worker output from Table 2 separately for Bottleneck and Non-Bottleneck firms. Panel A reports the treatment effect for the average worker, panel B reports heterogeneity by "Early" and "Late" workers, and column 1 replicates the spillover result for worker output from subsection 6.2. Columns 2 and 3 report results for 52 Bottleneck firms and 40 Non-Bottleneck firms. The overall effect on weekly output is larger in Bottleneck firms at 0.36 standard deviations (32% of the control mean, significant at the 1% level), compared to 0.12 standard deviations (12%, not statistically significant) for Non-Bottleneck firms.

More importantly, which workers gain from the incentives differs across the two samples. Column 2 of panel B reflects the same spillover pattern as in the full sample. In Bottleneck firms, all workers, *including* "Early" workers gain from the treatment. "Early" workers experience a 0.39 SD increase in weekly output (equivalent to 1,000 pieces and significant at the 5% level), and the effect for "Late" workers is similar in magnitude (0.34 SD) and not statistically distinguishable from the effect for "Early" workers. By contrast in Non-Bottleneck firms (column 3, Panel B), the effect is concentrated entirely among "Late" workers, who experience an additional 0.40 SD increase in weekly output, $\approx$ 1,400 additional pieces (although the total effect is 0.34 SD, with a p-value of 0.11).

These patterns replicate when I consider an alternate definition of hold-ups within the firm. Columns 4 and 7 of Table 3 report results for Complex Task and No Complex Task firms respectively. Recall, in Complex Task firms, tasks are less easily substitutable across workers, limiting the extent to which firm owners can re-assign tasks across workers. Similar to the result for Bottleneck firms, spillovers from "Late" to "Early" are only present in

Complex Task firms, where the firm is not able to cover for late workers: "Early" workers in Complex Task firms produce 0.40 SD more in weekly output (significant at 5% level), with no differential effect for "Late" workers (column 4, Table 3B). The effect in No Complex Task firms is driven by "Late" workers, who produce 0.19 SD more in weekly output (not significant), while there is no effect for "Early" workers.

Reassuringly, the labor supply response is consistent across both these definitions. The increase in timely arrival is driven by "Late" and "Very Late" workers in both samples (Figure 10).[21,22]

Both definitions of hold-up were not randomly assigned, and these sub-samples of firms differ along a few baseline characteristics. As shown in Table A20, Bottleneck firms are larger, have more machines and "Late" workers, and have higher monthly revenues and non-labor costs than Non-Bottleneck firms. Results are robust to including controls for the number of "Late" workers at baseline using an ANCOVA specification. [23,24]

Taken together, spillovers to "Early" workers, for whom the incentives were not binding, appear only in firms where lateness is more likely to create hold-ups. There are no spillovers in firms where lateness does not create hold-ups. This is consistent with the coordination mechanism, and is difficult to reconcile with alternative explanations for the output gains, such as peer effects from arriving together.

6.4 Total Firm Output

Increases in individual worker output translate almost one-to-one to increases in total firm output. I estimate treatment effects on total firm output using Equation 2 and report results in Panel A of Table 4.

[21] The effect on timely arrival is larger for "Early" workers in Bottleneck and Complex Task workers than in the average sample, but this increase seems to be driven by higher attendance rates for "Early" workers. This may imply that "Early" workers withheld their attendance at the firm because of hold-ups, although my design does not allow me to precisely test this hypothesis.

[22] Weekly worker earnings and output per hour (columns (2) and (3) in Table A16 and Table A17 respectively) exhibit the same pattern: all workers experience an increase in earnings and output per hour in firms where hold-ups are more likely (Bottleneck and Complex Task firms), though effects on earnings are imprecise.

[23] Bottleneck firms also have a larger number of active orders per day. This may be consistent with firms maintaining multiple orders in production to mitigate the effects of lateness. If that is true, the evidence that spillovers only appear in Bottleneck firms, and not in Non-Bottleneck firms further supports my hypothesis from section 3 that firms' adaptation to late arrivals is incomplete.

[24] There are fewer differences between Complex and Non Complex Task firms, except that the former are larger and have more machines. This difference may be driven by the presence of complex task workers themselves: since complex tasks are slower to complete, every firm typically hires multiple such tailors to match their pace with other workers on the line.

Total firm output, as measured by the sum of pieces stitched on all tasks, increases by 0.30 standard deviations (equivalent to 6,800 additional pieces stitched), a 29% increase relative to the control mean and is statistically significant at the 10% level (column (1)). Column (2) reports effects for the last task measure, which counts the total number of finished pieces. Total quantity of finished pieces in treatment firms increases by 0.21 standard deviations, equivalent to 700 additional pieces of finished output. This measure is noisier, possibly because the last task may be under-counted if orders are still under production in the last week of the experiment. Panel A of Table A18 reports these estimates after dropping the last week of data collection, and the magnitudes across both measures are similar. [25] Consistent with results on worker output, gains in total firm output are larger in Bottleneck and Complex Task firms (Column (1) of Table 4, Panels B and C).

The above two outcomes reflect worker-reported measures of firm output. The results are consistent with an alternate, owner-reported measure: the quantity of new orders received by firms. Treatment firms procure 0.27 standard deviations more new orders per week, a 21% increase relative to the control mean ($\approx$ 880 pieces), as shown in column (3) of Table 4. [26] While this measure is noisily estimated, its magnitude matches the worker-reported outcomes.

Finally, delays in order delivery are lower in treatment firms. The probability of completing an order after the planned delivery date falls by 10 percentage points, a 40% reduction relative to the control mean, as shown in column (4) of Table 4. Thus, increasing timely arrival at the firm facilitates timely completion of orders. This result holds in both Bottleneck and Non-Bottleneck firms, as suggested in section 3. The reduction in delays is larger in Non-Bottleneck firms: the probability of a delayed order falls by 19 percentage points, 76% relative to the control group mean and is statistically significant at the 10% level (Panel B, column (4) of Table 4). In Bottleneck firms, the reduction in delays is smaller (6 percentage points), and not statistically significant.

These results suggest that reducing late arrivals benefits both firms and workers. I show that these gains are materialized through a better functioning production line, timely completion of orders and by procuring more new orders in treatment firm. However, gains must be compared against the cost of incentivizing workers for timely arrival. The next section evaluates the profitability of incentives.

[25] Reassuringly, a third measure counting all but the last task on the production line (column (3) of Table A18) produces similar estimates.

[26] 98% new orders were delivered, so this indicates total pieces delivered by the firm as well.

6.5 Profitability of Incentives

Timely arrival increases both firm revenues and labor costs. Total weekly firm revenues (column 1 of Table 5) in treatment firms increased by INR 3,258, an 8% increase relative to the control mean (INR 39,000), and total labor costs *excluding* the incentives increase by INR 1,640, a 9% increase relative to the control mean (INR 17,843). This implies that if firms did not have to incentivize workers to achieve timely arrival, there would be a INR 1,617 increase in profits, about 8% of the control mean (column 5). This is statistically insignificant, but meaningful.

However, paying for these incentives costs more than the gain in revenues, resulting in a negative effect on weekly profits net of incentives equivalent to INR 981 (5% of the control mean, reported in column 6). Even if incentives were only paid to "Late" and "Very Late" workers (while not a feasible contract) there would be no gain in profits (column 7).

Thus, while timely arrival improves firm outcomes, the incentives I offered in the experiment are too costly for firms. Recall that the choice of 20% daily bonus in this experiment was to maximize the first stage response from workers. These results don't rule out the existence of other less costly contracts that could incentivize timely arrival.

6.6 Why do firms tolerate lateness?

The results from the experiment establish that timely arrive does improve worker and firm production. These gains are larger when late arrivals create hold ups on other workers, suggesting that coordination gains exist in these firms. Endline survey responses suggest that both firm owners and workers acknowledge these benefits, and attribute these gains to an increase in timely arrival (Figure 11).

However, only 26% said they would be willing to offer workers such incentives themselves, and were willing to pay INR 30 for a similar daily bonus on average (5% of daily earnings).[27] In the follow-up survey, there is no take up financial incentives by treatment firm owners indicating that treatment firms reverted to the status quo form of organization.

Thus, firms continue to tolerate lateness, and this reflects the large compensating differentials associated with incentivizing timely arrival. This is supported by two qualitative findings. First, workers strongly value flexibility in arrival times. 25% of workers in the sample are characterized as never-takers: workers in treatment firms who arrive late despite

[27] 19 out of 40 owners reported a willingness to pay of INR 0.

being offered incentives. These workers demonstrate a willingness to pay for flexibility of at least 20% of their earnings. Second, 55% report having worked in large, export factories that enforced strict work schedules, and left those jobs because they prefer work schedules.

This preference is strongly tied to time commitments workers have outside of work. As shown earlier, workers report arriving late because of household and care-giving responsibilities, activities that make up most of their time before the workday. Endline surveys with workers show that workers in treatment did not change their morning activities during the incentive weeks, but instead delegated those activities to others or spent less time them in order to arrive on time (Figure 12). Therefore these commitments reflect constraints on worker's time that may require broader market level interventions to shift workers' need and preferences for flexibility.

7 Conclusion

This paper experimentally tests whether irregular labor supply affects firm productivity in the context of a garment manufacturing cluster in India. I document that workers exercise considerable flexibility in when they arrive at work. At baseline, workers are late on 44% of worker days, and the 10-90 gap in worker arrival times is over 2 hours. This stands in contrast to firm owners' preference to have workers arrive at a common time, given the production line based organization of firms.

A daily bonus equivalent to 20% of worker earnings successfully increases timely arrival in treatment firms by 43%, resulting in a 17% decrease in dispersion in arrival times at the firm level. This is a meaningful effect given the small size of these firms – incentives increase the fraction of workers who arrive within the first 15 minutes of opening time from 60% (2 out of 4 workers) to 80% (3 out of 4 workers).

As a result of the incentives, weekly output per worker increases by 24% for the average worker. This partly reflects an increase in productivity (output per worker-hour), given the smaller increase in weekly work hours. More importantly, this increase is distributed equally among "Early" and "Late" workers in treatment firms, indicating the presence of positive spillovers since the timely arrival response was driven entirely by "Late" workers.

These spillovers are present in firms where lateness creates the largest hold-ups along the production line, thus reflecting gains from better coordination in production. Firms are also able to deliver orders with fewer delays, which is key for maintaining important client relationships. These gains translate almost one-to-one to total firm output, which increases

by 29%, and a 21% increase in new orders procured. Average weekly revenues increase by 8% in treatment firms, and accounting for labor costs without incentives yields 8% higher profits. These results suggest that lateness negatively affects firm outcomes.

However, the incentives I offered for coordinating worker arrival times are too high, and not profitable for firm owners. Not surprisingly, only 26% owners said they would be willing to offer such incentives themselves, and the average stated willingness to pay for a similar daily bonus was INR 30 – less than a third of the incentives that I offered in the experiment, indicating low willingness to pay. In a 3-12 month follow-up survey, I find no take-up of any kind of financial incentives by treatment firms, and little effort overall in enforcing timely arrival.

These results are consistent with a large compensating differential for incentivizing timely arrival in the local labor market where these firms operate, explaining why firms allow lateness in the status quo. Despite the 20% incentives, a substantial share of workers do not take-up the incentives, suggesting workers place a high value on flexibility in whether and when to arrive at work (Breza and Kaur, 2025). These preferences reflect constraints workers face on their time outside of work related to missing or thin markets for services such as childcare, transportation (public transit, school buses), or the quality of public infrastructure (municipal water supply). My results demonstrate the importance of policies aimed at improving the quality of such services as complementary to industrial policies.

Finally, in other survey work with workers across Tiruppur district, I document that the provision of flexibility varies systematically with firm size – small and medium firms are significantly more likely than large firms to offer their workers flexibility in work schedules. Consequently, there is sorting of workers into small (≤ 20 workers) versus large (> 20 workers) firms along gender, marital status and having children – characteristics that are positively correlated with demand for flexibility (Table A19). While workers who work in small firms enjoy flexible work schedules, they do so at the cost of variable pay and lack of access to formal government benefits, such as state provided health insurance, social security, etc. To the extent that demand for flexibility affects workers' labor supply choices, such as whether to be self-employed, work as casual day labor (Oh et al., 2024; Cefala et al., 2024), or work in small firms without formal benefits, this can have important implications for the rate of wage-employment in developing countries. More research is needed to understand the drivers of the demand for flexibility in developing countries, as well as the broader economic implications on the functioning of labor markets and firms in such settings.

8 Figures

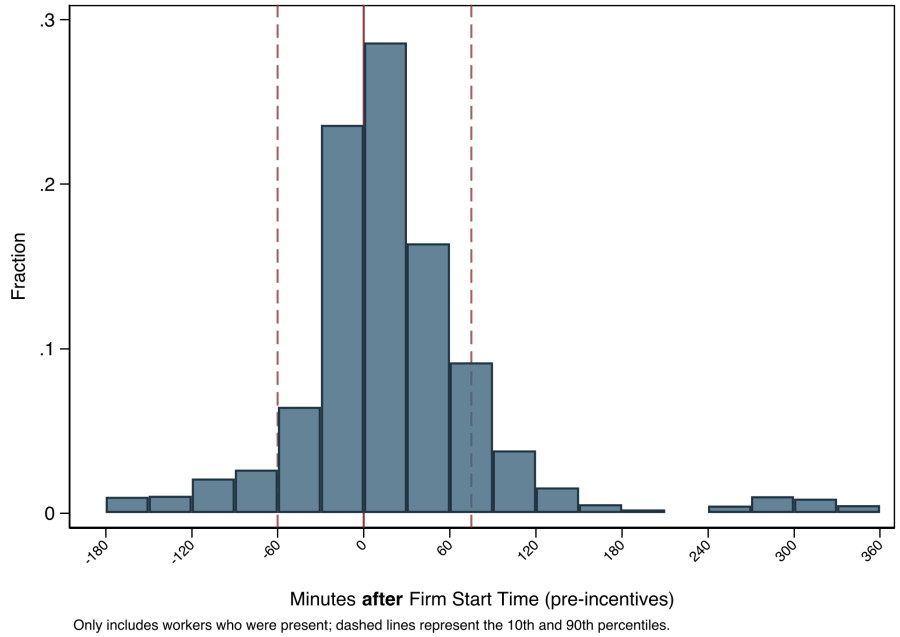

Figure 1: Stylized Production Line for T-Shirts

Notes: This figure presents a stylized example of a production line with 4 operations/tasks that make a T-Shirt. Firms receive cut panels of fabric which pass through a fixed sequence of stitching operations staffed by a distinct worker (tailor).

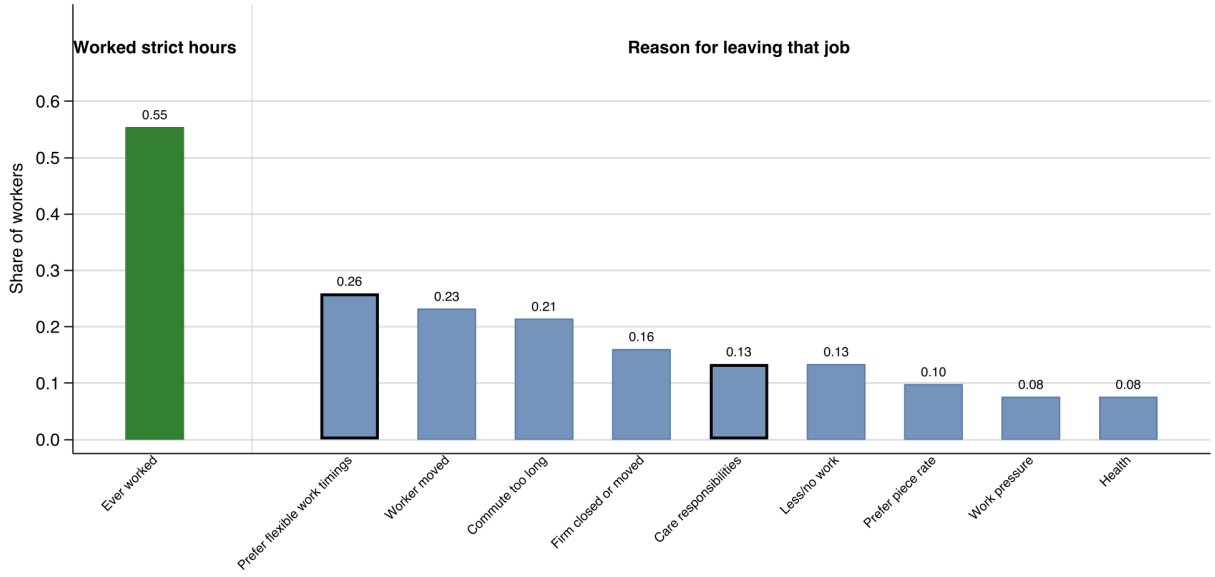

Figure 2: Worker Arrival Times Relative to the Owner's Preferred Start Time

Figure 3: Distribution of Arrival Times, Pre-Incentives

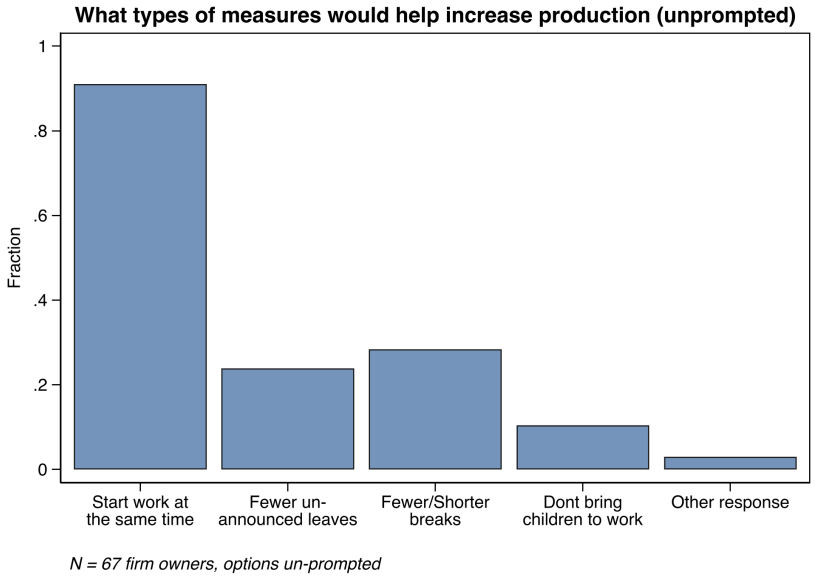

Notes: This figure plots the distribution of worker arrival times, in minutes relative to the owner's preferred start time, during the pre-incentive weeks in all 92 firms. The sample includes worker-days on which the worker was present. The solid vertical line marks the preferred start time; dashed lines mark the 10th and 90th percentiles (a 10-90 gap of 135 minutes).

Figure 4: Workers Have Left Jobs with Strict Work Hours

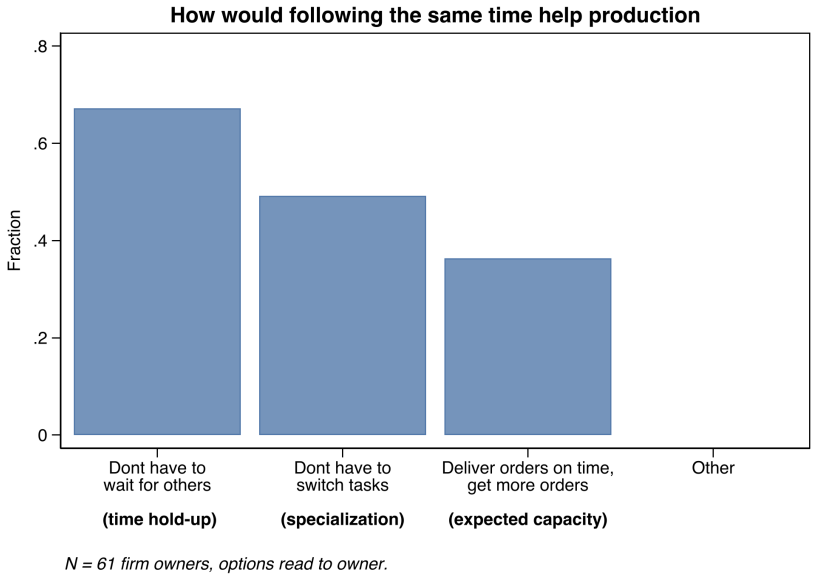

Notes: The left bar is the share of workers who ever worked a job with strict hours. The right bars are the reasons those workers left that job, as a share of workers who had one. Workers could select multiple reasons, so shares sum to more than one. Outlined bars mark the reasons tied to flexibility and care responsibilities.

Figure 5: Importance of Common Arrival Times (Baseline)

(a) Measures that could help increase production

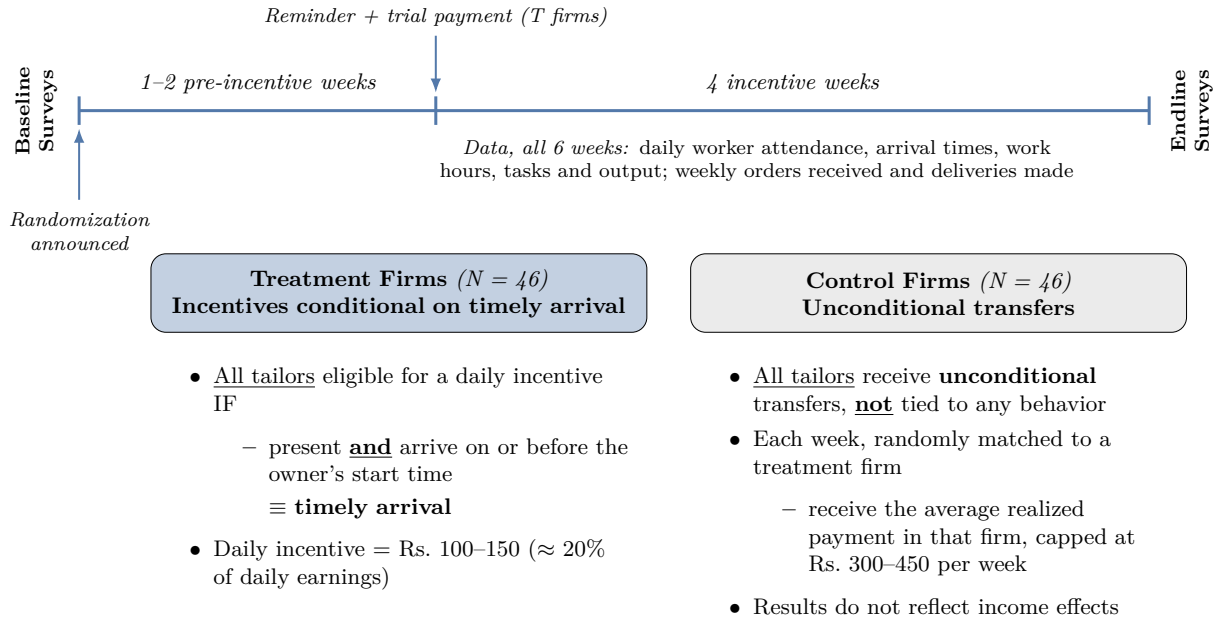

(b) Why is coordination in worker arrival times important

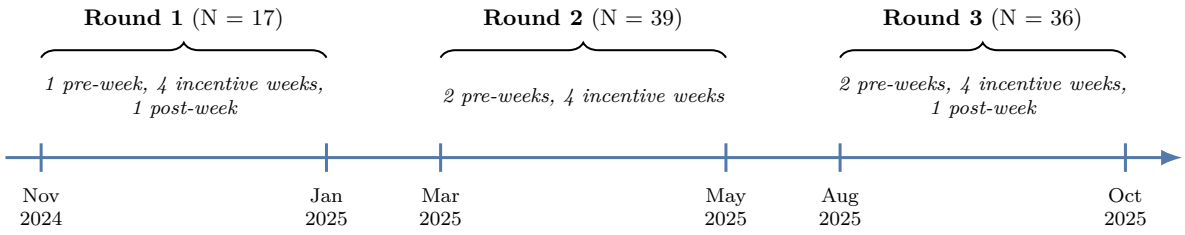

Notes: Panel A reports owner's responses from the question "*What type of measures would help increase production?*", with options unprompted. N = 71. Panel B reports owner's responses from the question "*If everybody starts work at the same time, how will it improve production?*", with options 1 = Workers don't have to wait for others, 2 = Workers don't have to switch tasks, 3 = Helps me fulfill orders on time and get more orders, and 4 = Others.

Figure 6: Experimental Design and Implementation Timeline

Panel A: Experiment Design

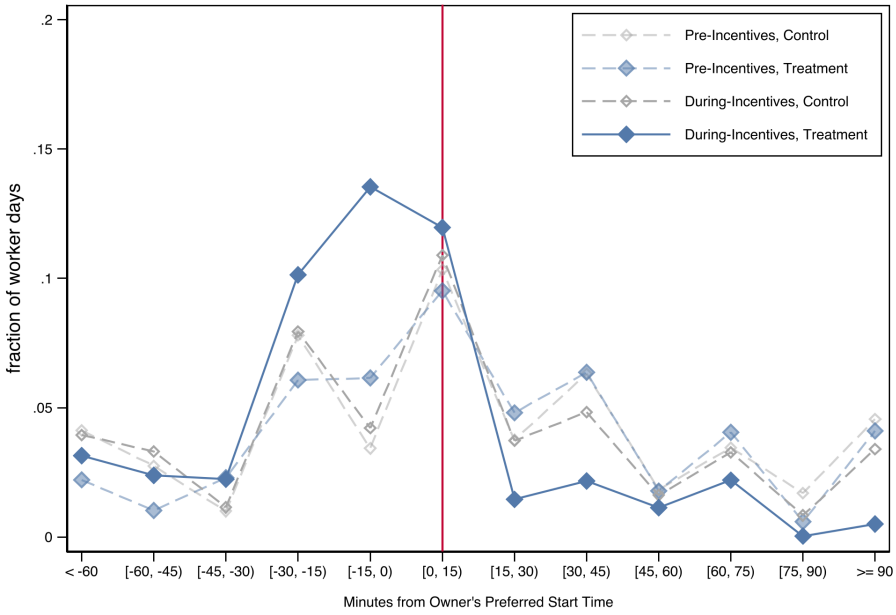

Panel B: Implementation Timeline

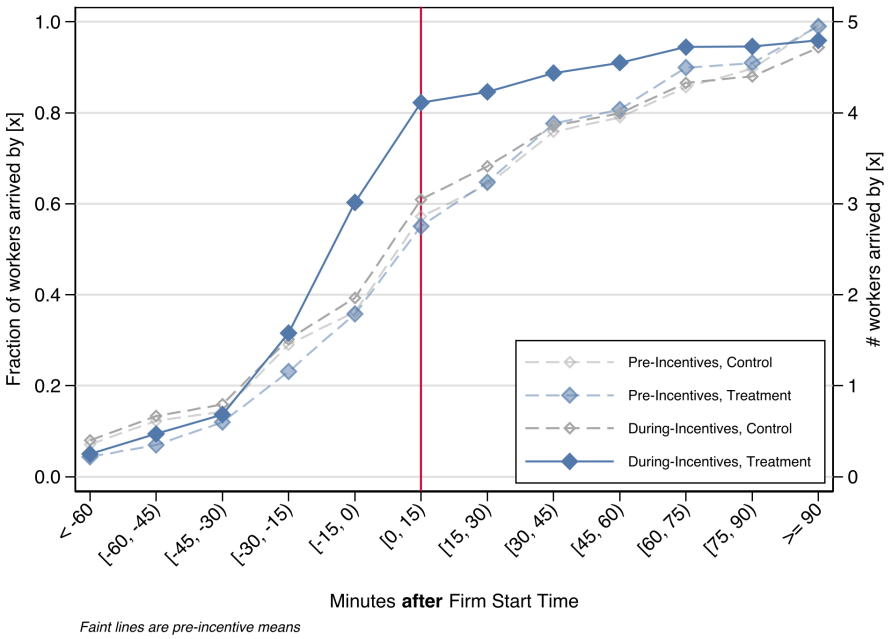

Notes: Panel A shows the 6-week study window in each firm and the two treatment arms. Panel B shows the three implementation rounds; N is the number of firms in the analysis sample in each round.

Figure 7: Treatment Effect on Worker Arrival Times

(a) Change in deviation from owner's preferred start time

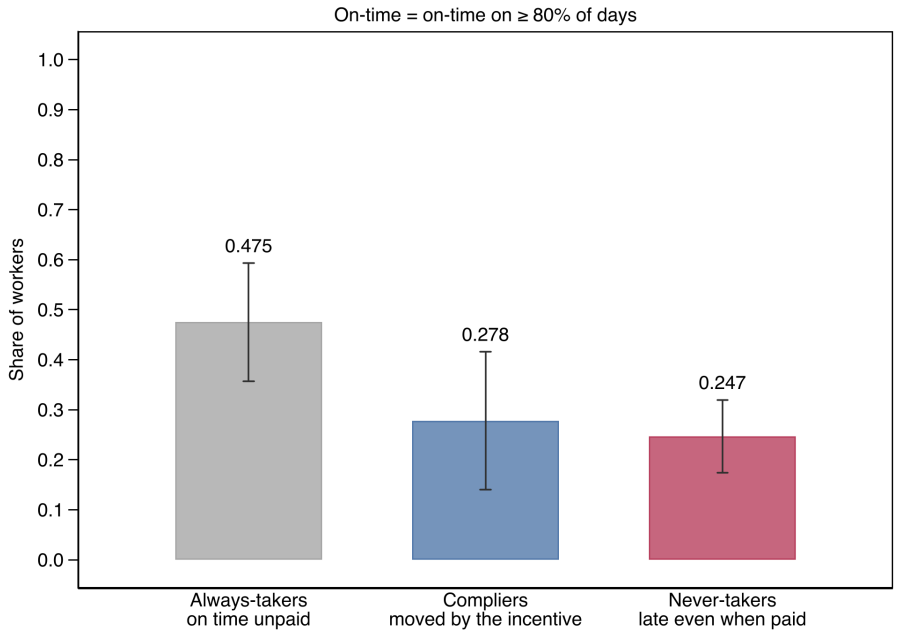

(b) Cumulative Share of Workers Arrived, by Treatment Status

Notes: Panel A plots the distribution of worker arrival times, binned in 15-minute intervals around the preferred start time, separately for treatment (blue) and control (gray) firms. Faint dashed lines show pre-incentive weeks; dark lines show incentive weeks. The sample includes worker-days on which the worker was present. The solid vertical line marks the preferred start time. Panel B plots the cumulative share of present workers who have arrived by each 15-minute interval around the preferred start time, separately for treatment (blue) and control (gray) firms. Faint dashed lines show pre-incentive weeks; dark lines show incentive weeks. The right axis reports the corresponding number of workers.

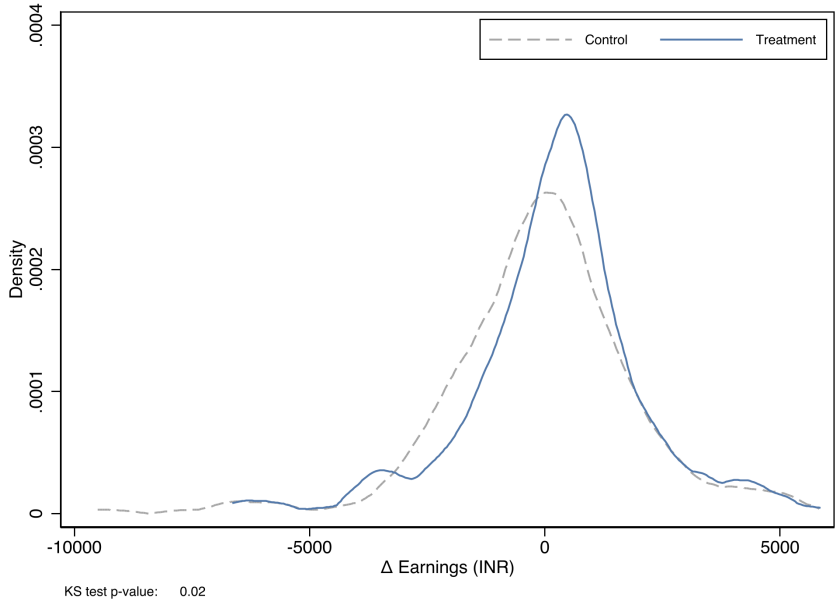

Figure 8: Always-Takers, Compliers and Never-Takers

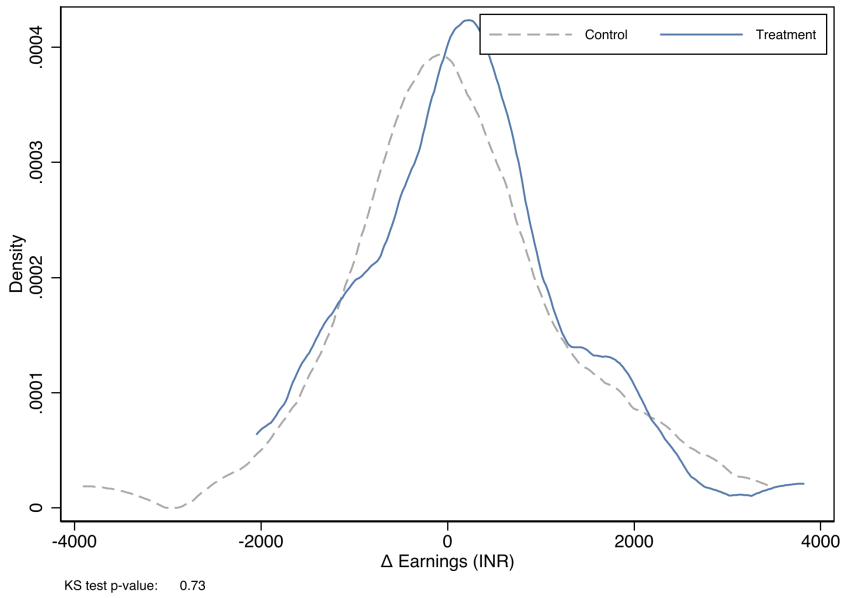

Notes: This figure decomposes workers by their response to the incentive during the four incentive weeks. A worker is on time if they arrive by the preferred start time on at least 80% of the days they are present. Always-takers are the share of control-firm workers who are on time; compliers are the increase in this share in treatment firms; never-takers are the share of treatment-firm workers who are not on time. Shares are estimated from a worker-level regression of the on-time indicator on treatment with strata fixed effects; bars show 95% confidence intervals with standard errors clustered at the firm level. The sample includes workers present on at least 5 incentive-week days. Treatment arms are pooled.

Figure 9: Distribution of the Change in Weekly Earnings

(a) Worker level

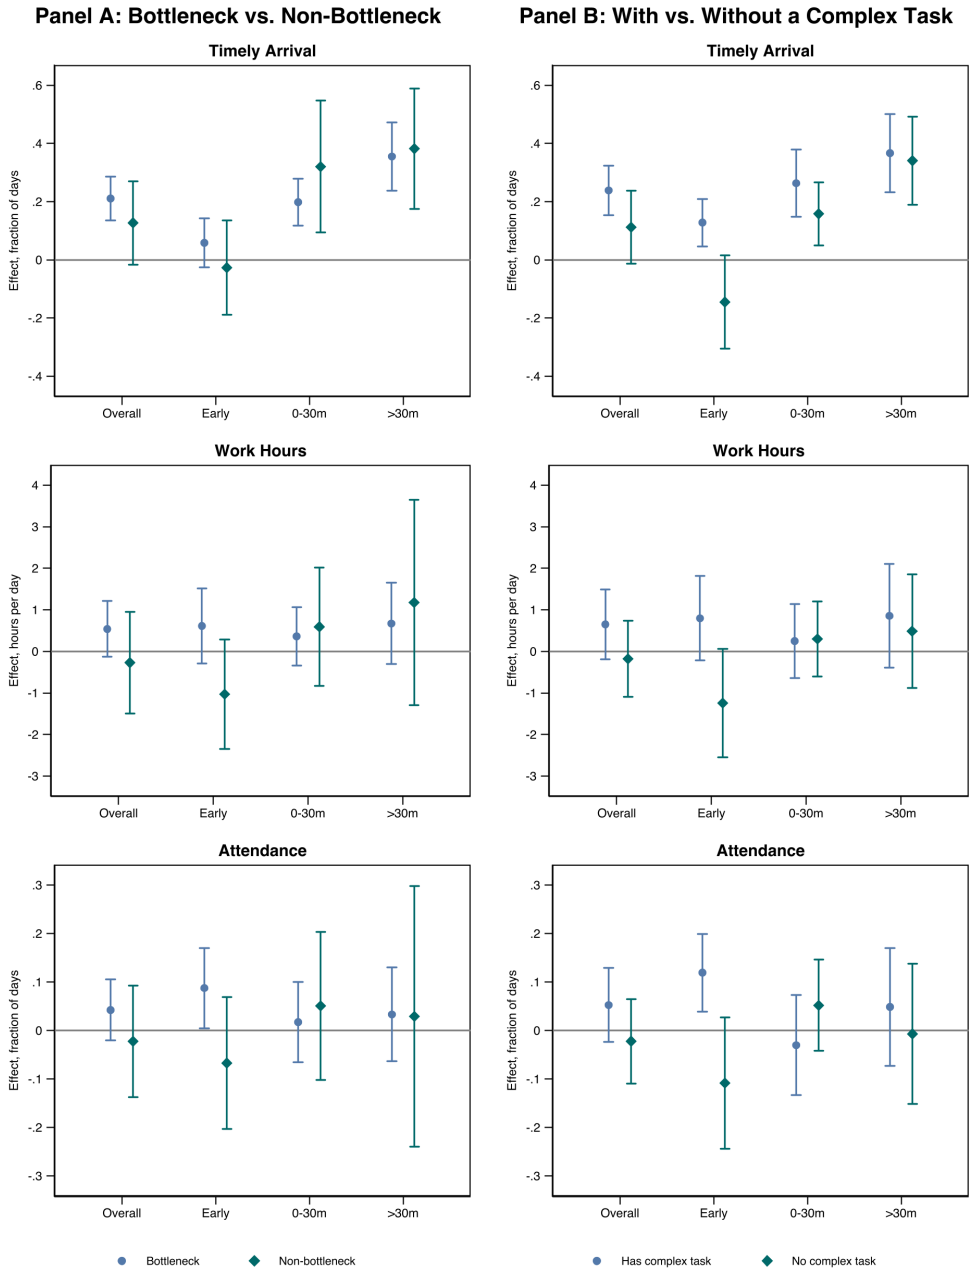

(b) Firm level

Notes: Kernel densities of the change in weekly earnings (INR, excluding incentives) between the pre-incentive and incentive weeks, for treatment (solid) and control (dashed) firms. Panel A: each worker's mean weekly earnings in the incentive weeks minus their mean in the pre-incentive weeks. Panel B: the firm average of the worker-level change. Earnings are coded as 0 for absent workers and winsorized at the 99th percentile. The KS test p-value is from a two-sample Kolmogorov–Smirnov test of equal treatment and control distributions.

Figure 10: Treatment Effects on Labor Supply by Bottleneck and Complex-Task Status

Notes: Each marker is the T × During coefficient from a separate regression on that group of firms, with a 95% confidence interval; standard errors are clustered at the firm level. Overall is the average effect; Early, 0–30m and >30m are the effects for workers who were early, 0–30 minutes late and more than 30 minutes late at baseline. Rows are outcomes. Panel A (left) splits firms by bottleneck status (at least one upstream worker late at baseline); Panel B (right) by whether the firm has any baseline complex (singer) task. Data at the worker-day level; all regressions include worker, day-of-week and round by week fixed effects.

Figure 11: Perceptions about the Experiment at Endline

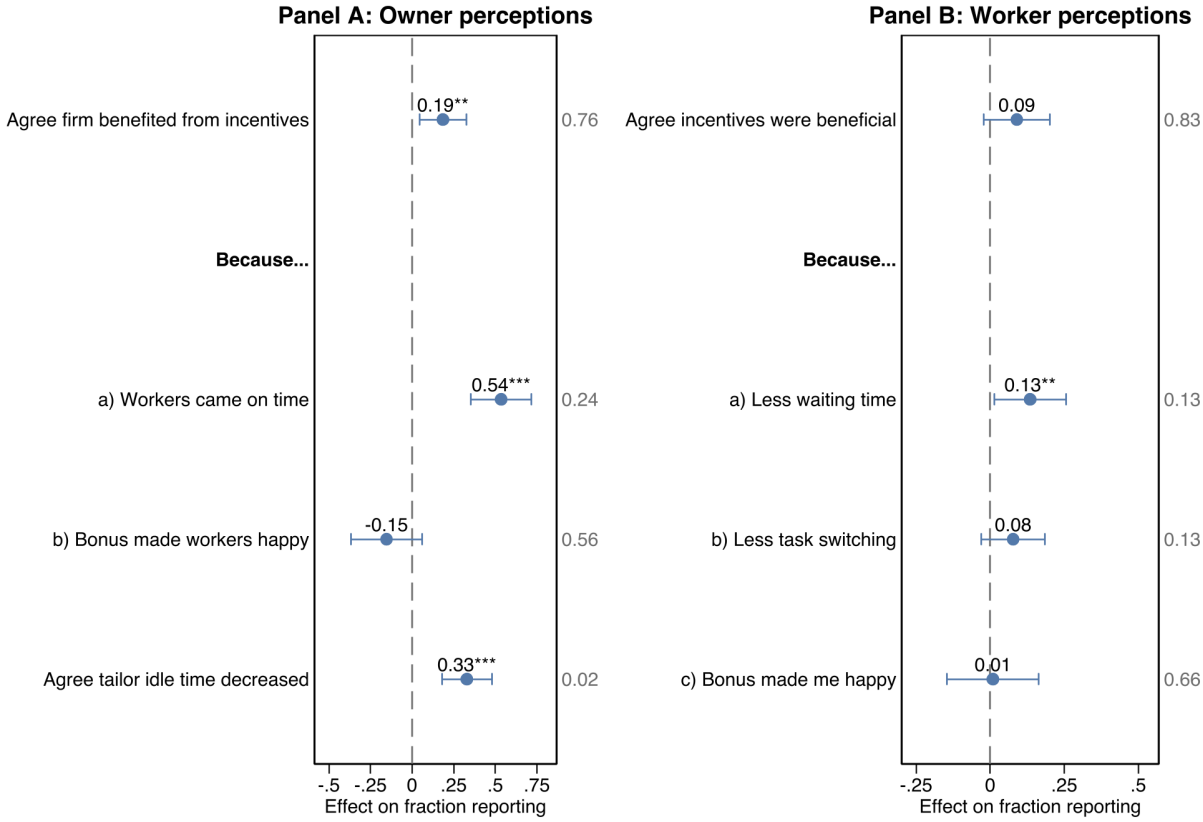

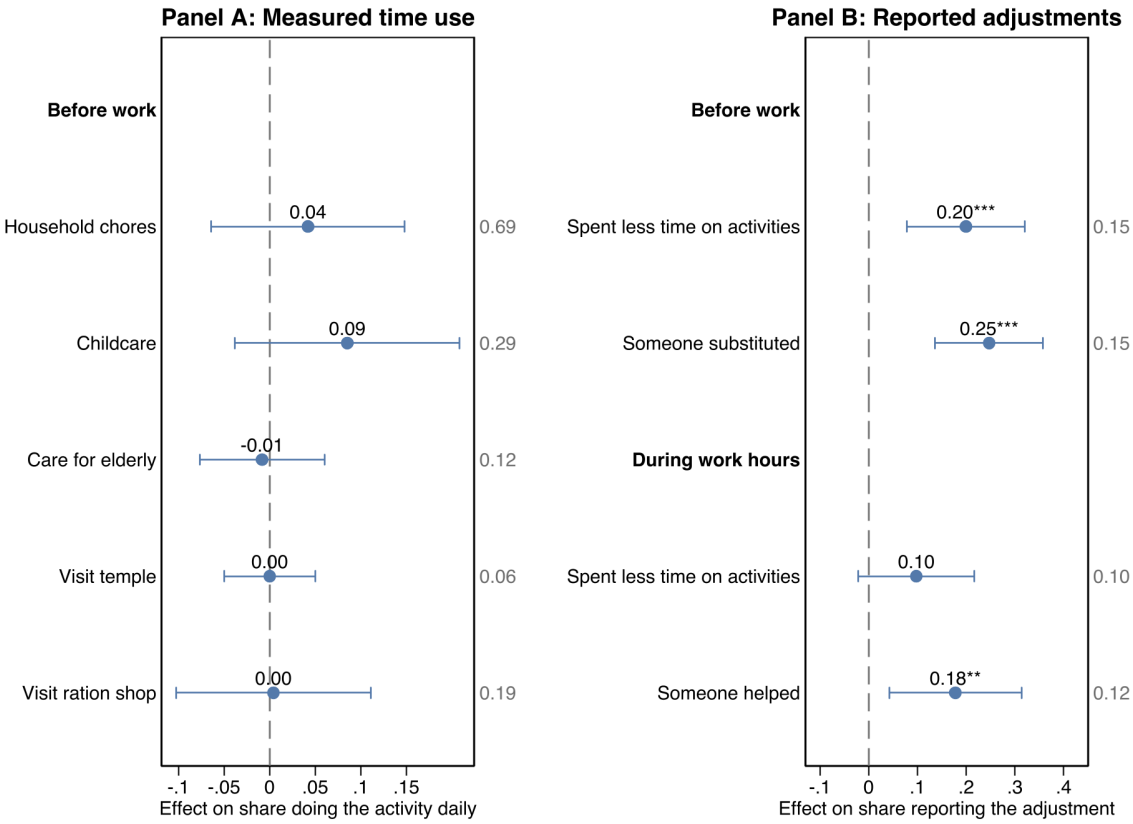

Figure 12: Treatment Effects on Worker Time Use and Reported Adjustments

Notes: This figure reports worker responses from the endline survey. Panel A reports treatment effects on whether the worker does each activity daily before work. Panel B reports treatment effects on whether the worker reports each adjustment to their activities before and during work hours. "Someone substituted" and "Someone helped" are from rounds 2 and 3 only. Each row is from a regression on a treatment indicator with strata fixed effects. Bars show 95% confidence intervals with standard errors clustered at the firm level. Numbers on the right are control means. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

9 Tables

Table 1: Treatment Effects on Labor Supply: Overall and by Baseline Lateness

	Timely Arrival		**Work Hours**		**Attendance**	
	(1)	(2)	(3)	(4)	(5)	(6)
Treatment × During	0.18***	0.01	0.28	-0.05	0.02	0.02
	[0.03]	[0.04]	[0.29]	[0.42]	[0.03]	[0.04]
Treatment × During × Late		0.21***		0.42		-0.01
		[0.05]		[0.47]		[0.05]
Treatment × During × Very Late		0.35***		0.78		0.00
		[0.06]		[0.51]		[0.05]
Control Mean (Pre-Incentives)	.41	.41	6.45	6.45	.71	.71
Omitted Group Mean (Pre-Incentives)		.69		7.42		.78

p-val Total Effect = 0		0.00, 0.00		0.26, 0.12		0.65, 0.55
Treatment Effect %	43	54, 88	4	6, 11	3	2, 4
Worker, Week FE	X	X	X	X	X	X
Day-of-week FE	X	X	X	X	X	X
N Worker-Days	17583	15852	16548	15272	17585	15853

Notes: All specifications include worker, day-of-week and round by week fixed effects. Standard errors are clustered at the firm level. Odd columns report the pooled treatment effect; even columns split it by the worker's average arrival delay in the pre-incentive weeks (Late = 0–30 minutes, Very Late = more than 30 minutes; the omitted group arrived on or before the owner's preferred start time). Attendance is defined as an indicator for whether a worker was present at the firm on that day. Timely arrival is defined as an indicator for whether a worker was present at the firm, *and* arrived by the owner's preferred start time on a particular day. The sample for these regressions excludes days on which a firm was shut, and no production took place. The lateness columns additionally drop workers with no measured baseline arrival time.
Total Effect reports the lincom of T × During plus the listed interaction (Late, Very Late shown comma-separated).
* $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$

Table 2: Weekly Output, Earnings and Output per Hour

	Weekly Output (SD)		**Weekly Earnings (INR)**		**Output (SD) per Hour**

Worker, Week FE	X	X	X	X	X	X
N Worker-Weeks	2663	2663	2663	2663	2398	2398

Notes: SEs clustered at firm level. All specifications include worker and round by week fixed effects. This regression excludes (a) owners/co-owners who also do stitching work at the firm, and (b) days of firm closure if no production took place at the firm. Output is normalized by product relative to pre-incentive week means. Earnings are coded as 0 for absent workers. Output and earnings are winsorized at the 99th percentile. Output per hour is normalized weekly output (in SD units) divided by weekly work hours, on weeks the worker is present; coefficients are in SD per hour, while the control mean and SD rows are in raw pieces per hour. Late pools all workers late at baseline. Total Effect reports the lincom of T × During plus the Late interaction.
* $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$

Table 3: Worker Output: Bottleneck and Complex-Task Splits

Weekly Worker Output (SD units)							
		Bottleneck		Complex Task			
	All Firms	**Bottleneck**	**Non-Bottleneck**	**Any Complex**	**Complex Downstream**	**Complex Upstream**	**No Complex**

Worker, Week FE	X	X	X	X	X	X	X
N Worker-Weeks	2663	1728	935	1495	929	566	1153
N Firms	92	52	40	44	27	17	47

Notes: SEs clustered at firm level, in brackets. All specifications include worker and round by week fixed effects. The sample is workers (excluding owners/co-owners who also stitch) and excludes days of firm closure when no production took place. Output is normalized by product relative to pre-incentive week means and winsorized at the 99th percentile. Columns are estimation samples, each a separate regression. Bottleneck firms have at least one upstream worker late at baseline. Complex-task firms produce at least one baseline style with a complex (singer) task; in Complex Downstream firms the complex task follows a simple task in at least one baseline style, and Complex Upstream are the other complex-task firms. p-values test equal average effects from one regression with a separate T × During per group plus group × During. Panel B interacts T × During with *Late*, an indicator for workers late at baseline. Total Effect p-value tests T × During + Late interaction = 0.
* $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$

Table 4: Treatment Effects on Weekly Firm Output, New Orders and Order Delays

	Firm Output (SD) (worker-reported, daily)		**New Orders (SD)** (owner-reported, weekly)	**Delayed Order** (owner-reported, per order)

Firm, Week FE	X	X	X	X
N Firm-Weeks	520	520	387	
N Orders				970
N Firms	91	91	85	86

Notes: SEs in brackets, clustered at the firm level. Columns (1)–(3) are at the firm-week level and include firm and round by week FEs. Firm output counts pieces across all tasks on the production line (column 1) or at the last task, i.e. finished pieces (column 2). New orders are owner-reported material receipts, standardized to pre-incentive product-level means. Column (4) is at the order level: an order is delayed if delivered more than one day after its planned delivery date. Orders are indexed by planned delivery week, orders whose planned window straddles the start of the incentives are dropped, and the regression includes firm and round by planned-delivery-week FEs. Panels B and C report the total effect of Treatment × During separately for each group of firms, from one regression that interacts Treatment × During and During with the group indicator. Bottleneck firms have at least one upstream worker late at baseline. Complex-task firms produce at least one baseline style with a complex task. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$

Table 5: Treatment Effects on Weekly Firm Revenue, Labor Cost and Profit

		Labor Cost (INR)			**Profit (INR)**

N Firm-Weeks	525	525	525	525	525	525	525
N Firms	92	92	92	92	92	92	92

Notes: SEs in brackets, clustered at the firm level. Data at the firm-week level; all regressions include firm and round by week FEs. Revenue and labor cost are computed on finished pieces (the last task on the production line). Profit is revenue less labor cost. Columns (3) and (6) add the incentive payments made during the incentive period to labor cost and subtract them from profit; columns (4) and (7) count only the payments to workers late at baseline. Panel B interacts Treatment × During with an indicator for bottleneck firms (at least one upstream worker late at baseline). * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$

A Appendix Tables and Figures

Table A1: Flexible Work Timings and Owners' Concerns About Enforcement

	Mean	SD	N
Panel A: Baseline Survey			
Firm is flexible with work timings	0.85	(0.36)	92
Workers follow the same start time	0.24	(0.43)	75
Accepts a tailor arriving 5 minutes late	0.92	(0.27)	92
Accepts a tailor arriving up to 30 minutes late	0.87	(0.34)	92
Accepts a tailor arriving more than 30 minutes late	0.79	(0.41)	92
Panel B: Endline Survey – Expected Consequences of Imposing Work Timings			
Workers will leave the firm	0.53	(0.50)	90
Workers less willing to work extra hours	0.39	(0.49)	90
Harms relationship with workers	0.31	(0.47)	90
Workers less willing to accept payment delays	0.06	(0.23)	90
Other	0.11	(0.32)	90

Notes: Panel A reports owner responses from the baseline survey. "Workers follow the same start time" is from rounds 2 and 3 only. Panel B reports owner responses from the endline survey to: "Suppose you started to impose morning work timings without any incentive. What would happen?" Owners who answered that workers would leave were asked for a second consequence; each row counts owners who named the consequence in either answer, so shares sum to more than one. Responses do not differ between treatment and control firms (all $p > 0.70$, from a regression on a treatment indicator with strata fixed effects and robust standard errors).

Table A2: Day-to-Day Persistence of Arrival Behaviour (Pre-Incentives)

	On time today		**Arrival deviation (mins)**	
	(1)	(2)	(3)	(4)
On time on previous day	0.534***	0.044		
	[0.023]	[0.027]		
Arrival deviation, previous day (mins)			0.560***	-0.027
			[0.032]	[0.036]
Mean of Dep. Var.	0.42	0.42	5.10	5.21
Intra-class correlation (worker)	0.47	0.47	0.56	0.56
Adjusted R^2	0.298	0.479	0.338	0.564
Observations	4,585	4,583	2,983	2,963
Day-of-week, Phase-week FE	X	X	X	X
Strata FE	X		X	
Worker FE		X		X

Notes: Data at worker-day level, includes pre-incentive weeks (-1 and 0) in Treatment and Control firms. The dependent variable is an indicator for arriving on time (columns 1–2) or deviation in arrival time defined as minutes after the owner's preferred start time, winsorised at 5/95 (columns 3–4). The regressor is the worker's own outcome on the firm's previous production day. Columns 2 and 4 add worker fixed effects. Intra-class correlation is the share of variance in the dependent variable explained by stable differences across workers. SEs in brackets, clustered at the firm level. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$

Joint F-test p-value				0.644

Notes: This table reports means, mean differences by treatment group and p-values for baseline firm and owner characteristics. Mean differences and p-values are estimated using a regression of each variable on an indicator for treatment with phase x strata fixed effects, with robust standard errors. The joint F-test p-value is from a regression of treatment on all balance variables with strata fixed effects and robust SEs; missing values in weekly output, revenue, and profits are mean-imputed within strata for this test only.

Day-of-week FE	X	X	X	X	X	X
Firm-order FE	X	X	X	X	X	X
N	7460	4466	2970	2002	1198	806

Notes: Data at worker-order-day level, pre-incentive weeks + control firms. This table reports results from a regression of daily output and earnings for worker i, working on order o on day d on an indicator for whether another worker performing an upstream task on the same order arrived late that day. Columns 1 and 4 report results for both midstream and downstream workers, while remaining columns separate the two samples. Cols. 1–3 use all such days; cols. 4–6 restrict to firm-days with one active order. All specs include worker, day-of-week, and firm-order fixed effects; SEs clustered at firm level, in brackets. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$

Table A7: Simple vs Complex Singer Tasks

Statistic	Source	Simple	Complex	p-value
Fact 1: *Complex tasks take longer to complete*				
5-minute test output (pieces)	Productivity test	20.95	8.86	0.00
Pieces per hour	Production data	105.1	36.3	0.00
Fact 2: *Complex tasks are paid higher piece rates*				
Worker piece rate (INR per piece)	Production data	0.78	2.16	0.00
Fact 3: *Complex tasks are done by specialised singer tailors*				
Operates singer machine (share)	Worker baseline	0.05	0.92	0.00
Share of task-days on own task type	Production data	0.97	0.84	0.00
Share of task-days on other task type	Production data	0.01	0.05	0.06
Fact 4: *Complex-task tailors arrive earlier, and are less likely to be female*				
Minutes after preferred start time	Attendance data	12.5	-21.2	0.00
Early (share)	Attendance data	0.38	0.74	0.00
Female (share)	Worker baseline	0.60	0.16	0.00

Notes: This table compares simple (power-table) and complex singer tasks and tailors in the pre-incentive period (week ≤ 0). Facts 1 and 2 are at the firm-task level (1,549 simple and 165 complex firm-tasks), except pieces per hour. Facts 3 and 4 and pieces per hour are at the worker level. Workers are grouped by their modal task in the pre-incentive period (361 simple-task and 61 complex-task tailors). 5-minute test output is from the productivity test on the corresponding task, averaged across weeks. Shares of task-days are computed over each tailor's pre-incentive task-days. p-values are from a regression of each statistic on an indicator for complex tasks (tailors), with firm fixed effects and standard errors clustered at the firm level.

Table A8: Bottleneck and Complex-Task Firms

Panel A: Treatment and Firm Classification				
	Bottleneck	Complex Task	Complex Downstream	Complex Upstream
Control mean	0.52	0.47	0.33	0.13
Treatment mean	0.61	0.50	0.26	0.24
T - C	0.08	0.04	-0.05	0.09
p-value	0.42	0.68	0.59	0.24
Firms	92	91	91	91

Panel B: Overlap of Bottleneck and Complex-Task Firms (Firm Counts)					
	No Complex	Complex Downstream	Complex Upstream	All Complex	Total
Non-bottleneck	21	12	6	18	39
Bottleneck	26	15	11	26	52
Total	47	27	17	44	91
Share bottleneck	0.55	0.56	0.65	0.59	0.57
Correlation (bottleneck, complex task)			0.04		
Fisher exact p-value			0.83		

Notes: Panel A regresses each firm classification on a treatment indicator with strata fixed effects and robust standard errors. Bottleneck firms have at least one upstream worker late at baseline. Complex-task firms produce at least one baseline style with a complex (singer) task. In complex-downstream firms, the complex task follows a plain-tailor task in at least one baseline style; the remaining complex-task firms are complex-upstream. Panel B reports firm counts. The correlation is between the bottleneck and complex-task indicators; the p-value is from Fisher's exact test.

Firms (Control / Treatment)	24 / 28			22 / 18			21 / 23			24 / 23		

Notes: This table reports balance between treatment and control firms within four subsamples. Bottleneck firms have at least one upstream worker who was late at baseline. Complex-task firms produce at least one baseline style with a complex (singer) task. For each subsample, the table reports the control mean (SD in parentheses), the treatment–control difference, and its p-value. Differences and p-values are from a regression of each variable on a treatment indicator with strata fixed effects and robust standard errors.

Table A10: Treatment Effects on Deviation from Start Time

	Deviation from Start Time (mins)	
	(1)	(2)

Treatment Effect %	-200	-219, -484
Worker, Week FE	X	X
Day-of-week FE	X	X
N Worker-Days	12437	12308

Notes: All specifications include worker, day-of-week and round by week fixed effects, from the specification in Equation 1. Standard errors at clustered at the firm level. The sample for these regressions excludes days on which a firm was shut, and no production took place. Total Effect reports the lincom of T × During plus the listed interaction (Late, Very Late shown comma-separated). * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$

Table A11: Treatment Effects on # and Duration of Breaks

	# Breaks		Total Break Duration (mins)	
Treatment × During	0.16	0.06	3.63	1.62
	[0.10]	[0.14]	[3.16]	[4.32]
Treatment × During × Late		0.07		1.16
		[0.17]		[5.29]
Treatment × During × Very Late		0.30*		6.93
		[0.15]		[5.32]
Control Mean (Pre-Incentives)	1.85	1.85	59.26	59.26
Omitted Group Mean (Pre-Incentives)		2.19		67.95
Total Effect (T × During + Inter.)		0.14, 0.36		2.78, 8.55
p-val Total Effect = 0		0.30, 0.02		0.49, 0.08
Treatment Effect %	9	7, 19	6	5, 14
Worker, Week FE	X	X	X	X
Day-of-week FE	X	X	X	X
N Worker-Days	17585	15853	17585	15853

Notes: Data at worker-day level. Outcomes coded 0 if worker was absent. Standard errors at clustered at the firm level. Total Effect reports the lincom of T × During plus the listed interaction (Late, Very Late shown comma-separated). * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$

Table A12: Treatment Effects on Worker Exit Times

Worker, Week FE	X	X	X	X	X	X	X
Day-of-week FE	X	X	X	X	X	X	X
N Worker-Days	12425	8145	4280	6956	4368	2588	5386
N Firms	92	52	40	44	27	17	47

Notes: SEs clustered at firm level, in brackets. All specifications include worker, day-of-week and round by week fixed effects. Data at the worker-day level, on days the worker is present; owners/co-owners who also stitch and days of firm closure are excluded. The outcome is an indicator for doing any non-production (helper) task or other work at the firm that day. Columns are estimation samples, each a separate regression. Bottleneck firms have at least one upstream worker late at baseline. Complex-task firms produce at least one baseline style with a complex (singer) task; in Complex Downstream firms the complex task follows a simple task in at least one baseline style, and Complex Upstream are the other complex-task firms. p-values test equal average effects from one regression with a separate T × During per group plus group × During. Panel B interacts T × During with *Late*, an indicator for workers late at baseline. Total Effect p-value tests T × During + Late interaction = 0.
* $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$

Table A14: Treatment Effects on Helper Attendance - Firm Level

	Fraction Helpers Present
	(1)
Treatment × During Incentives	0.03
	[0.04]
Control Mean (Pre-Incentives)	.83
Control Mean (Incentive Weeks)	.81
Treatment Effect %	4
Firm, Week FE	X
Day-of-week FE	X
N Firm-Days	3039

Notes: This table reports firm-day level outcomes on helper attendance. All specifications include firm, day-of-week and round by week fixed effects. Standard errors are clustered at the firm level.
* $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$

Table A15: Weekly Worker Earnings

	Weekly Earnings (INR)

Firm, Week FE	X	X	X	X
N Firm-Weeks	430	430	430	328
N Firms	91	91	91	85

Notes: SEs in brackets, clustered at the firm level. Data at the firm-week level; all regressions include firm and round by week FEs. Firm output counts pieces across all tasks on the production line (column 1) or at the last task, i.e. finished pieces (column 2). Column (3) counts pieces at all tasks except the last. New orders are owner-reported material receipts, standardized to pre-incentive product-level means. Panels B and C report the total effect of Treatment × During separately for each group of firms, from one regression that interacts Treatment × During and During with the group indicator. Bottleneck firms have at least one upstream worker late at baseline. Complex-task firms produce at least one baseline style with a complex task. Restricted to weeks 1–3 of the incentive period. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$

Table A19: Flexibility by Firm Size

	Small Firms		Large Firms	
	Mean	SD	Mean	SD

Observations	40	52		47	44	

Notes: This table reports means and SDs of baseline firm and owner characteristics by firm group. Bottleneck firms have at least one upstream worker late at baseline; complex-task firms produce at least one baseline style with a complex (singer) task. p-values are from a regression of each variable on the group indicator with strata fixed effects. Robust standard errors.

Figure A1: Reasons for Lateness and Time-Use Before Work

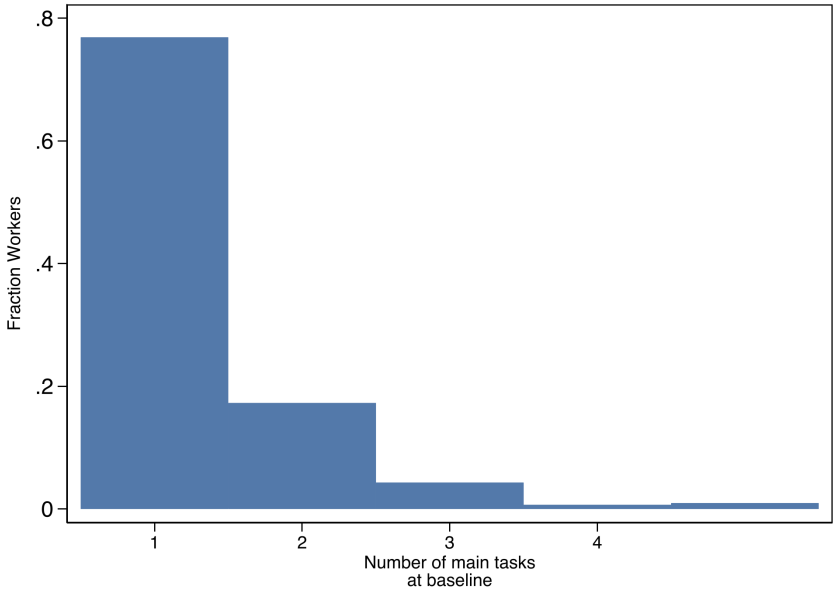

(a) Reasons for arriving late

(b) Time use before work, by gender

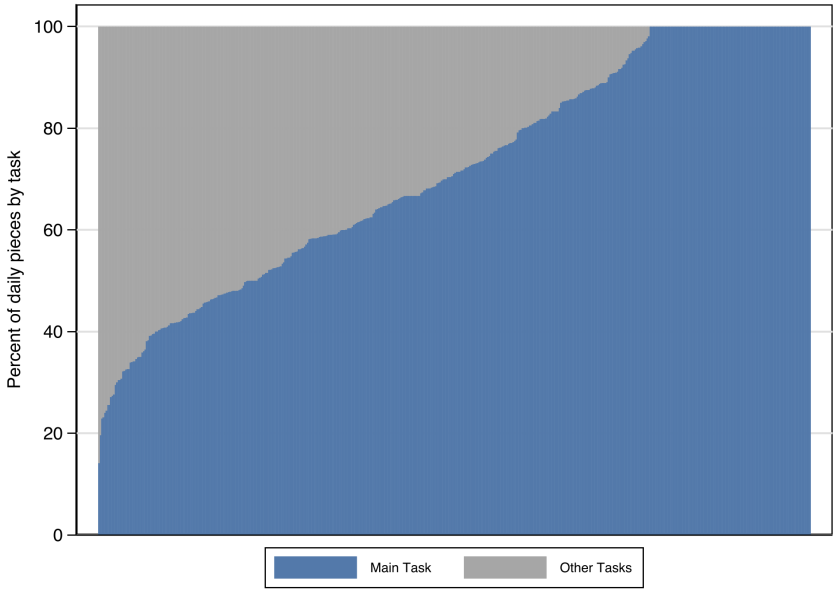

Notes: The figure in panel A reports the share of workers selecting each reason for not arriving on time in the week before the endline survey, among the 45 control workers (14 firms) who were observed to be late at least once. Transportation arrangements pools person who drops me was busy/late" and public transportation delayed"; lost track of time pools forgot to come on time" and lost track of time". Since this question was asked at endline, the figure only includes control-firm workers. Panel B reports the share of workers who report doing each activity before their workday starts, at baseline, separately for male and female workers. Dark bars show the share who do the activity every day; white bars show the share who do it once a week. Household chores pools collecting water, cooking, washing clothes, washing vessels and other household work; childcare pools helping children get ready and dropping off or picking up children. This module was asked in rounds 2 and 3 only (456 workers: 193 male, 263 female)

Figure A2: Number of Main Tasks per Worker

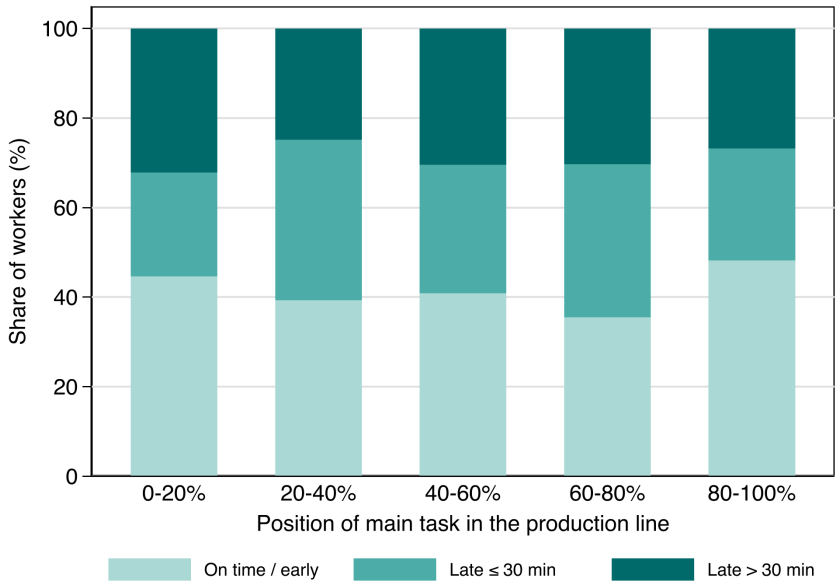

Notes: This figure shows the distribution of the number of main tasks per worker. For every worker, I define a "Main Task" as a task that I observe the worker performing every day she was present in a given pre-incentive week.

Figure A3: Task Specialization

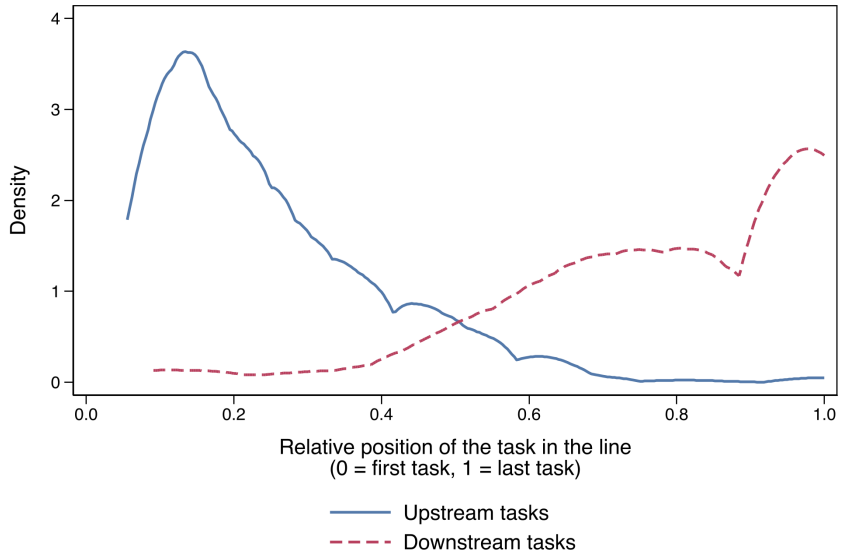

Notes: Each bar is one worker. This figure shows the share of each worker's daily pieces from their main task and from all other tasks, averaged over pre-incentive days. A worker's main task is defined as the task that I observe that worker performing every day she was present in a given pre-incentive week. Workers with more than one main task have all main tasks counted together.

Figure A4: Baseline Lateness by Position of Main Task in the Production Line

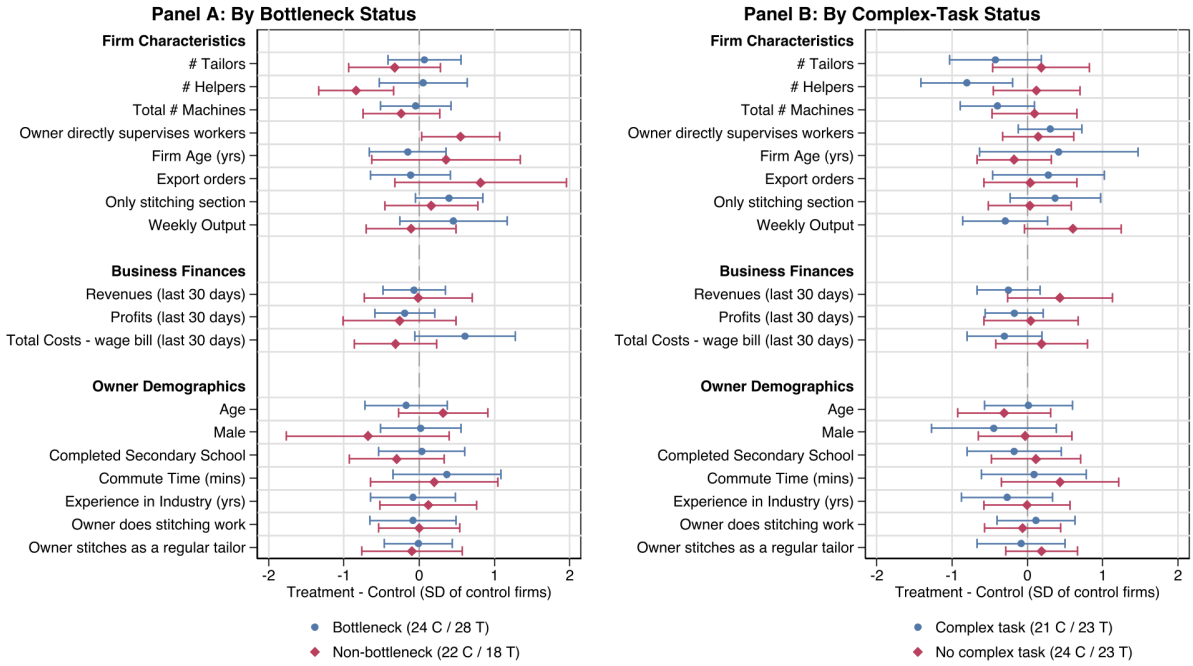

Notes: This figure plots the share of "Early", "Late" and "Very Late" workers by the position of their main task in the production line. Task order is divided by 9, the median number of tasks per product, and capped at 1, so that relative task order denotes fifths of the production line.

Figure A5: Position of Upstream and Downstream Cut-off Tasks in the Production Line

Notes: This figure plots the distribution of the relative position in the production line of tasks classified as upstream cut-off tasks (solid line) and downstream cut-off tasks (dashed line). Relative position is a task's order in the production line divided by the total number of tasks for that product (0 = first task, 1 = last task). Upstream cut-off tasks are tasks that must be completed before remaining tasks can proceed (e.g., attaching shoulders on a t-shirt); downstream cut-off tasks are tasks that must be completed for a garment to be finished (e.g., bottom hems on a t-shirt, or elastic bands on pants). Data from the baseline style rosters.

Figure A6: Balance on Baseline Firm Characteristics Within Firm Subsamples

Notes: This figure reports balance between treatment and control firms within four subsamples. Bottleneck firms have at least one upstream worker who was late at baseline. Complex-task firms produce at least one baseline style with a complex (singer) task. Each marker is the treatment–control difference from a regression of the characteristic on a treatment indicator with strata fixed effects and robust standard errors, divided by the SD among control firms in that subsample, with a 95% confidence interval. Panel labels report the number of control (C) and treatment (T) firms in each subsample. Owner supervision is omitted for Bottleneck firms because all control firms in that subsample supervise.

Figure A7: Self-Reported Idle Time among Workers
